After-treatment.—For the first 12 hours half-ounce feeds of glucose ♏ xl. and sod. bicarb. gr. x. with water by the mouth; glucose saline enemata were given every two hours. Thereafter small feeds up to the point of tolerance were given. More than half an ounce given at any one feed during the first week produced regurgitation of non-projectile type.

Comparison of Cases.

Weight.—Case 1: Four ounces were gained in the first week. The weight fluctuated until the fourteenth day and then steadily increased. Case 2: The weight remained stationary until the fifteenth day, when an increase at the rate of 1¾ ounces a day began.

Bowels.—Case 1: Bowels opened on the day following operation; but the stools did not become normal until *the fourth week after operation.* Case 2: *Bowel moved* on the second day and by the sixth day the stool was almost normal.

Temperature, rectal.—Case 1: Rose to 100° F. on the fourth day and was subnormal by the sixth day. Case 2: Rose to 101° F. at 2 A.M. on the morning following operation, and fell to subnormal by the evening of the same day. With increase of weight in both cases the temperature level rose slightly nearer the normal line. These temperatures are interesting, since they differ markedly from the clinical temperature chart published by Gray and Pirie, who show that a pyrexia ranging from 103° to 105°, falling to normal in four to five days, is usual after Ramstedt's operation. The difference in type we attribute to the state of the gastric mucosa at the time of the operation. Case 1 was operated on six days after the onset of vomiting, whereas Case 2 was operated on 19 days after onset, so that the consequently greater dilatation of stomach and the more unhealthy condition of the mucosa, shown by the emesis of brownish fluid on the morning of operation, are regarded as the causes of the modified pyrexia.

The immediate post-operative change for the better in the infants' appearance was very striking. The mother of Case 2, in commenting on it, remarked that even if the result were adverse she would never cease to be grateful for the relief that operation gave.

Anæsthetic.—The good judgment of the anæsthetist in his choice of anæsthetic and in its administration to such debilitated and unstable subjects is of extreme importance in the surgical treatment of congenital hypertrophic pyloric stenosis. In both cases cited above we were fortunate to have the experience and skill of Dr. Dudley W. Buxton.

Choice of Operation.

In Case 1 Ramstedt's operation was the only procedure possible, owing to the smallness and debility of the infant. In dealing with Case 2, the choice was influenced first by the quickness with which the operation could be performed, and secondly by the autopsy findings of Rachford, who noted that six months after a Ramstedt operation the pylorus showed no trace of tumour; and by *their confirmatory evidence in the* cases examined post mortem by Gray and Pirie. Subdermic infusions of saline and glucose were not given. An empty, healthy colon and rectum ought to absorb sufficient fluid to relieve thirst and to satisfy the tissues to the point of surgical safety. Moreover, the obvious dangers of infusion and the annoyance of operating through œdematous tissues were avoided. Diarrhœa appears to be one of the dangers incident to post-operative treatment, and therefore feeding must be carefully studied.

The dilated unhealthy stomach of a case treated medically for three weeks or so, no matter how conscientiously washed out, is a fruitful source of acid fermentation. The coexistent inhibition of the pancreatic function tends to further fermentation. Small amounts of predigested food are therefore necessary. Peptonised milk has been empirically advised by Hutchinson, Gray and Pirie, and others. We found, however, that even very small amounts of peptonised milk (dr.ii. to dr.iv.) were not well tolerated. In theory one would expect *a greater tendency to* diarrhœa with an acid food passing into the intestine unneutralised by the strongly alkaline pancreatic secretion. In practice we are confident that this is the case. In our cases the diet consisted of diluted Nestlé's milk predigested by papain (Martindale) and sod. bicarbonate, the result being an alkaline, non-irritating, non-septic, palatable food which was greedily taken and well tolerated. It might be argued that an alkaline food would tend to delay the re-establishment of pancreatic function, and that what is gained on the one hand is lost on the other; but this argument is clinically of little importance.

Conclusions.

1. That in view of the proof that the congenital tumour persists in adult life, medical treatment can merely relieve the condition and that only in a small percentage of cases.
2. That early surgical treatment is indicated in all cases where hypertrophic pyloric stenosis has been diagnosed.
3. That Ramstedt's operation appears to be the only procedure which restores the pylorus to a condition approaching the normal.
4. That the general practitioner accustomed to surgical technique can successfully perform Ramstedt's operation even in the most severe cases of pyloric stenosis.

Boxmoor.

THE STANDARDISATION OF TUBERCULIN.

BY A. J. EAGLETON, M.D. LOND.

(*From the Wellcome Physiological Research Laboratories.*)

TUBERCULIN has at present three chief uses: (1) the testing of cattle for tuberculosis; (2) the diagnosis of tuberculosis in man; and (3) the treatment of tuberculosis in man. Tuberculin prepared in the usual way has often been found inefficient for (1) and (2), and inactive preparations have doubtless been used in treatment. The standardisation of such a drug is then of great importance; the object of this communication is to show the degree of accuracy with which it may be done.

The various methods of standardising tuberculins are based on Koch's original discovery that tuberculous animals show a characteristic reaction when injected with doses of tuberculin which are quite innocuous to the normal animal. The official Frankfort[1 2] test is essentially identical with that of Koch; a similar test is used in Vienna. The Bureau of Animal Industry, Washington, U.S.A.,[3] employs a slight modification of the original method. There is at present no official test in Great Britain.

In this paper is described the test as applied in this laboratory, with the difficulties presented and the degree of accuracy permitted by its use. The subcutaneous test, which is a modification of the Frankfort test, will first be considered. The improvements introduced in the intradermic and von Pirquet tests will then be reviewed. Finally, a résumé will be given of all tests carried out with the tuberculin which we employ as our standard.

Preliminary sensitisation.—A batch of guinea-pigs of approximately equal weight, and from 50 to 70 in number, is injected intramuscularly with a saline suspension of tubercle bacilli (1 mg. per c.cm.). Half a cubic centimetre is injected into the anterior and inner aspect of the right thigh, deep to the adductor muscles. The right inguinal region of the injected guinea-pigs is examined periodically for enlargement of the lymphatic glands; any animals that may die from extraneous causes are carefully searched for signs of infection. After about 21–30 days glandular enlargement will be appreciable; we can then proceed to the preliminary test, which is as follows.

1. *Subcutaneous Test.*

Into one animal of the batch 0·5 c.cm. of a tuberculin which has remained constant in value for a long period and is used as a "standard" is injected under the skin of the abdomen. If death occurs within 24 hours with typical lesions, then the main test can be undertaken. Should the animal survive, or should the post-mortem findings be atypical, then a further preliminary test must be made at a later date, and so on, until a typical death is obtained.

The main test consists in the comparison of a sample with the standard tuberculin. Doses of 0·5 c.cm., 0·25 c.cm., 0·1 c.cm., 0·05 c.cm. of each tuberculin are injected, and the lowest dose found that will produce a fatal result in 24 hours with typical post-mortem signs. At least two animals must be injected with the "minimal lethal dose." The following scheme will explain the procedure:—

Batch X., injected 0·5 mg. standard strain tubercle bacilli.

Preliminary Test.

25 days later	0·5 c.cm.	Standard tuberculin	S.
7 " "	0·5 c.cm.	" "	D. 2 days.
7 " "	0·5 c.cm.	" "	D.o.n.

Main Test.

C.cm.	Standard.	Sample A.	Sample B.	C.cm.	Standard.	Sample A.	Sample B.
0·5	D.o.n.	D.o.n.	S.	0·05	S.	S.	—
0·25	D.o.n.	D.o.n.	S.	0·05	S.	S.	—
0·1	D.o.n.	D.48 hs.	S.				
0·1	D.o.n.	S.	—	2·0	—	—	S.
0·1	D.o.n.	S.*	—	1·0	—	—	S.

S. = survived; D. = death; o.n. = overnight. * Seedy.

Sample A is just under standard strength, while sample B is useless. The minimal lethal dose of the standard varies with the batch of animals, as will be shown later; the samples can only be appraised by comparison with the standard on the same batch of animals. In other words, no absolute value can be given to any tuberculin as the reagent employed to test it is a variable. As much as 5 c.cm. of the standard has been injected into non-tuberculous guinea-pigs without giving rise to any result except the immediate irritation, due to the glycerine content of the inoculum.

The main difficulty in connexion with this test lies in the fact that different batches of animals vary in the time which they take to become sensitive to the tuberculin. It will be seen later that the individual members of a batch vary so little in sensitivity that it is rare to find any aberrant deaths or survivals when testing serial dilutions of tuberculins. The different batches, on the other hand, show variation, both in the length of time taken to become sensitive and in the degree of sensitivity attained, as judged by the minimal lethal dose of standard tuberculin.

The earliest period at which any batch is sensitive can only be found by a preliminary test as described above, and in some batches as many as five such tests have been negative. Again, if 0·5 c.cm. of standard kills one or two animals of a batch we have to inject lower doses to find the degree of sensitivity present; in this way many animals are wasted. In order to obviate this difficulty we tried both the von Pirquet and intracutaneous tests parallel with the subcutaneous test. As a result of many experiments we found a correlation between the three methods, as shown in the table (*vide infra*).

2. *The von Pirquet Test.*

Von Pirquet himself studied the cutaneous reaction of tuberculous guinea-pigs to tuberculin; he states that these animals are not very sensitive to the drug, and that a deeper scarification is necessary than that used for the test in human beings. Our experiments confirm this, but we found that when deep scarification was used the resulting trauma sometimes made the reactions difficult to read. We changed our method of scarification from two intersecting parallel lines to two and finally three parallel scratches ///, and the "three-scratch" test is the one we now employ. With this method the trauma is not sufficient to obscure the reaction, and well-graduated readings can be obtained with different dilutions of tuberculin on the same animal. Before the tests, a white area of the animal is deprived of hair by clipping and the application of a calcium sulphide paste, after which the area is washed with warm water and the animal thoroughly dried. The groups of three scratches are spaced out as far as possible. Different dilutions of the tuberculins are applied to the areas, and glycerine broth, ten times concentrated as in the preparation of the tuberculin, is used as a control. The reactions can be read in 24 hours, and have generally diminished by 48 hours.

3. *Intracutaneous Reaction.*

The intracutaneous reaction was first described in 1905 by Mantoux, Moussu, and Römer, and adopted later by Loewenstein, but is not used in any official laboratory.

The test consists in the injection of 0·1 c.cm. of diluted tuberculin into the skin of the shaven area. As in the von Pirquet test, we have always used a control of broth, but in this case diluted 1/10. The reactions cannot be read in 24 hours, taking three days to reach their maximum development. The control injection gives a transitory reaction, but this fades by the second or third day, while the different dilutions of tuberculin give rise to lesions of varying intensity. In the most marked, a central area of necrosis is surrounded by a bright red halo, the whole mounted on an œdematous disc with a sharply defined border. The slighter degrees are marked by diminishing necrosis until the end-point consists merely of a small raised disc; often, however, there is a sudden transition from a lesion showing necrosis to a completely negative reaction.

The von Pirquet and intracutaneous tests can be used for the standardisation of tuberculins, but hitherto we have always checked the results so obtained by the subcutaneous method. The skin reactions are, however, indispensable in experimental work, where we have a large number of samples made in different ways, where the available material is small, or where we must test for small traces of active principle. It should be pointed out that in all cases where the skin tests are used alone, a control and the standard must be included on the same animal as the samples under experiment. Slight individual variations occur in the members of a batch. These are due partly to the differences in the skin trauma, and partly to the fact that the skin reactions, being more delicate, detect variations which do not affect the subcutaneous test.

The value of the von Pirquet test as a guide to the sensitivity of a batch, and the comparison of the skin reactions with the subcutaneous test, are shown in the following table:—

Batch XV.

19/6/20.—0·5 mg. *B. tuberculosis* H12, injected intramuscularly into batch of animals.

8/7/20.—Von Pirquet test: standard tuberculin undiluted +, control −; 1/10 (+).

12/7/20.—Same animal as above, standard 0·5 c.cm., subcut. D.o.n.

15/7/20.—Von Pirquet:

	Tuberculin.		Broth.
	Standard.	Sample A.	Control.
Undiluted	++	+	−
1/5	(+)	−	
1/10	−	−	

23/7/20.—Von Pirquet:

	Standard.	Sample A.	Control.
Neat	++	+	−
1/5	++	(+)	
1/10	+	−	
1/20	?	−	

Intracutaneous (72 hours reading).

	Standard.	Sample A.	Control.
1/5		++	−
1/10		++	
1/15		++	
1/20		−	
1/50	++		

24/7/20.—Subcutaneous:
Standard 0·25 c.cm. D.o.n. Sample A 0·5 c.cm. D.o.n.
0·25 c.cm. S.

3/8/20.—Subcutaneous:
Standard 0·1 c.cm. D.o.n. Sample A 0·5 c.cm. D.o.n.

4/8/20.—Standard 0·05 c.cm. D.o.n. Sample A 0·5 c.cm. D.o.n.
0·05 c.cm. S.; seedy. 0·25 c.cm. S.

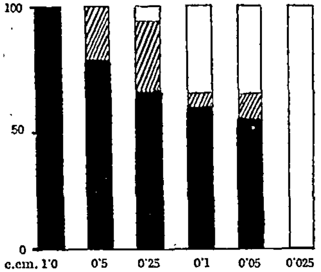
++ = Very strong. + = Strong. } Von Pirquet reaction.
(+) = Slight. − = Negative. }

4. *Constancy of Test.*

Since August, 1919, when our present standard was adopted, 13 different batches of animsls have been infected with a constant dose of the same culture. Of these animals 91 have received doses of standard ranging from 1·0 c.cm. to 0·025 c.cm. In only two cases were irregular results produced with animals of the same batch—that is, a low dose killed, while a higher dose was ineffective. The individual variation of members of the same batch gives an error then of just over 2 per cent.

The constancy of the test on all batches is shown in the diagram. It represents animals injected with tuberculin at least 30 days after infection. The tops of the black columns show the percentage of deaths at each dose. The tops of the shaded columns show the increased percentage of deaths since we have employed the von Pirquet test to indicate the dosage for subcutaneous inoculation.

Diagram showing Dose in Cubic Centimetres.



Dark columns show percentage of deaths at each dosage. Shaded columns show percentage improvement after adoption of von Pirquet reaction.

The following factors must be controlled if accurate results are to be obtained: (1) the same strain of tubercle bacillus must be used for injecting the animals; (2) the guinea-pigs should be about the same size; (3) all animals to be given injections of tuberculin should be examined and any sick ones discarded—no animal should be used unless the inguinal glands are palpable; (4) the von Pirquet test should be used to guide the dosage for subcutaneous injection.

The results show that tuberculins can be tested with a reasonable degree of constancy. They also show the value of the von Pirquet test as an adjunct to the subcutaneous test. It may, I think, also be claimed that the standard in use in this laboratory has been thoroughly tested and is suitable for this reaction. We have tested tuberculins made in 1889 and since that date, and many of the earliest samples are still potent. We are, however, at work on the exact standardisation of a purified, dried tuberculin, which may, if satisfactory, be used as a standard in future.

In conclusion, I have to thank Dr. Stanley Griffiths for his kindness in sending us our standard culture, and all my colleagues for criticism, suggestions, and help. Above all, I am indebted to Dr. R. A. O'Brien, who initiated this work and placed at my disposal his knowledge of the test derived from long experience.

CZECHO-SLOVAK MEDICAL DELEGATES AT BRIGHTON.—The delegates of the Ministry of Health of Czecho-Slovakia, on their return from studying health methods in America as guests of the Rockefeller Foundation, visited Brighton on Feb. 15th. They were specially interested in its sanitary administration and its general health activities. Dr. Duncan Forbes, the medical officer of health, showed them his system of work, and visits were paid to the Sanatorium School Clinic and Tuberculosis Dispensary, and to the estate where a big housing scheme is in process of development.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A PROBABLE CASE OF CEREBRAL VENTRICULAR HÆMORRHAGE, ASSOCIATED WITH MARKED AND PERSISTENT CONVULSIONS.

BY E. J. PARRY, M.R.C.S., L.R.C.P. LOND.,

AND

O. K. WILLIAMSON, M.D. CANTAB., F.R.C.P. LOND.

THE following case is of interest on account of (1) the intensity and persistence of the convulsions, and (2) the diminution in the degree of unconsciousness followed by a relapse into complete coma.

At 11.30 P.M. on March 14th, 1920, Mr. Parry was summoned to see a gentleman, aged 45 years, who had just previously been seized with a fit whilst in a warm bath. Dr. Williamson was called in and arrived at 12.30 A.M. on the 15th. The patient was then practically unconscious, with insensitive conjunctivæ and pale, livid face. His condition of marked general tonic rigidity soon gave place to a general clonic spasm, left arm being flexed at the elbow, right arm extended with rolling and scratching movements of fingers of right hand. Lower extremities extended, the mouth slightly open, and tongue, which was clean, alternately protruded and retracted, the pupils equal and rather dilated. Pulse full, rather rapid, apparently not of high tension. Superficial arteries neither tortuous nor thickened. Heart normal, respiration stertorous. At one time the degree of unconsciousness became less marked and patient uttered inarticulate sounds. At about 1.30 A.M. the rigidity became much less marked, for the spasm which had alternately increased and diminished had by now lessened. The colour of the face was now better than it had been; about this time patient passed a very offensive motion. The pupils became normal in size; the respirations quieter, and at about 2.30 A.M., when both doctors left the house, the degree of unconsciousness certainly seemed to be less profound than it had been.

At 8 A.M., however, Mr. Parry found the patient to be completely unconscious, the left pupil minutely contracted, the right dilated; there was complete paralysis, and he died soon after 9 A.M.

The clinical picture at the time we left the house at the end of the first visit was that of a severe epileptic seizure, but the subsequent course puts a different interpretation upon the case. Any question of poison may be ruled out, and although perhaps uræmia cannot be absolutely excluded, the clinical course is best explained by a hæmorrhage from a branch of the middle cerebral artery, with rupture into the ventricle. A necropsy was not obtained. A history was obtained from the patient's wife that on three previous occasions, at intervals of about a year (the last time about a year before the fatal illness), attacks had occurred which the attending doctor considered to be epilepsy, and each of which necessitated a day's rest in bed.

A CASE OF DIAPHRAGMATIC HERNIA.

BY A. E. KEOWN, M.B. BELF.

CASES of this rare condition are reported from time to time in the literature. As a rule a portion of the stomach or intestines passes through the diaphragm into the left pleural cavity and symptoms follow which call for urgent operative interference.

Sapper M. W., 106th Co., R.E., was hit by a bullet in the left posterior axillary line below and to the outer side of the lower angle of the left scapula. This happened at Moquet Farm, Pozières, on the French front. He fell, and was carried to a station where he coughed up blood through most of the night. He was X rayed at Boulogne, and again at the Endell-street Hospital, where he lay five weeks, but no bullet was seen. After this there was constipation, and at times flatulence and hiccough. On August 14th, 1920, he came to me complaining of cramp-like pains beginning to left of umbilicus, and reaching nearly to left shoulder. He had had a restless night, and had vomited a bitter green fluid. He had been given an enema with some result. There was no retention of urine. Examination of the abdomen caused the pains to recur. There followed borborygmi, and the pain was easier. This sequence could be elicited and followed each time the abdomen was palpated. Temperature and pulse normal.

On the 15th the abdomen was distended and very prominent to the right of the umbilicus. The enemas were being returned uncoloured and all borborygmi had ceased. It was evident that a partial obstruction was now complete and he was sent into the Merthyr General Hospital. A high enema was given there but without result. He did not look very ill. The absence of vomiting and of an intestinal ladder seemed to indicate that the obstruction was in the large bowel.

On the 19th Mr. R. S. Ryce opened the abdomen through a median incision and the large intestine appeared, looking like liver and greatly distended. A rubber tube was tied in and it collapsed, permitting further examination. The colon was then found to leave the abdomen at its splenic flexure. The opening in the diaphragm was easily enough enlarged with the fingers and a portion of the bowel pulled down. There were firm adhesions that prevented the return of all the bowel; moreover, the patient's condition did not justify any further operative procedure, and the abdomen was closed. For a few days fæces were passed through the tube as well as per rectum, and then it was removed.

The patient, a blacksmith, has been warned that he will have to seek lighter work. He complains now at times of flatulence, and it is not improbable that another operation may be required to free the adhesions, return the prolapsed colon, and repair the diaphragm. To do this really well it seems to me imperative to resect at least two ribs and so get at the diaphragm from above. Mr. Ryce tells me that the opening in the diaphragm was circular and well to the left of the œsophagus, also that it was not connected with either arcuate ligament and that it was just such an opening as might have been made by a bullet.

Llwynwern, Glam.

TWO CASES OF RELAPSING FEVER.

BY ROBERT NIXON, M.B., CH.B. LIVERP.

THE following cases of spirochætal relapsing fever occurring in Liverpool are of interest in view of the large number of emigrants from Eastern Europe now passing through our ports:—

The patients, H. S. and B. S., two Roumanian boys, aged 15 and 11 respectively, were admitted to the City Hospital South, Liverpool, on Nov. 26th, 1920, from an emigrants' boarding-house with the diagnosis of measles. The history was as follows: They left Roumania on Nov. 9th, and arrived in Liverpool, via Prague and Hamburg, on Nov. 23rd. They were not deloused at Hamburg. Neither of the boys showed any signs of illness on the voyage, but the elder, H. S., complained of headache and malaise shortly after landing. The younger boy had appeared in normal health up to the time of admission to hospital. No rash had been noticed on either.

H. S. on admission had a temperature of 103° F. which rose the *following morning to 105°, accompanied by expectoration of about* an ounce of "rusty" sputum, and fell by crisis the same evening to 98°. Nothing abnormal could be found in the lungs and no tubercle bacilli or pneumococci in the sputum. The younger boy, B. S., appeared in normal health on admission. However, his temperature rose to 102° on Dec. 2nd, and the following day H. S.'s fever recurred, again accompanied by expectoration of "rusty" sputum. Blood smears taken on Dec. 4th showed in each case spirochætes throughout the field in large numbers, exceedingly thin and in length about three or four times the diameter of a red blood corpuscle. H. S.'s blood still showed spirochætes on Dec. 6th; but all subsequent smears from B. S. were negative.

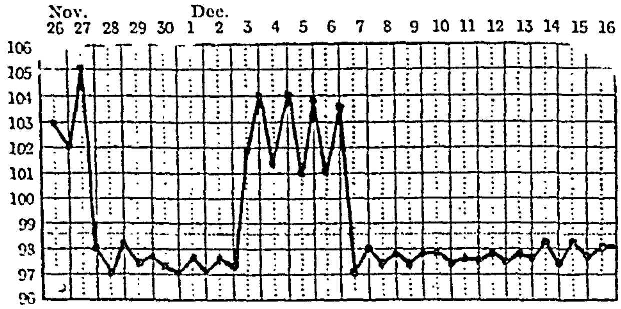

CHART 1.—H. S., aged 15.

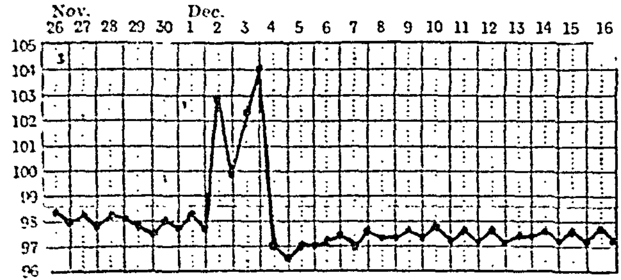

CHART 2.—B. S., aged 11.

Neither boy has had any relapse since Dec. 7th, and both were discharged from hospital in good health and apparently completely recovered.

Liverpool.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

SKIN DISEASE: ITS RELATION TO INTERNAL DISORDER.

A MEETING of this society was held on Feb. 14th, Sir FREDERICK W. MOTT being in the chair, when a discussion took place on this subject.

The opening papers, by Sir JAMES GALLOWAY and Professor ARTHUR HALL, are given in full in the front part of THE LANCET of last week and the present issue respectively.

Dr. E. W. GOODALL said that he based his remarks upon an experience derived solely from an acquaintance with

Skin Affections connected with Acute Infectious Diseases

of this country. The eruptions met with in the acute infectious diseases were acute and transient and variable, from a fleeting urticaria to a pustule which left a scar. The cutaneous phenomena of the acute infectious diseases were met with at different stages of an attack, but, as a rule, certain skin manifestations were met with at certain stages. They might be arranged in three groups: (1) the prodromal or initial rashes, (2) the eruptions characteristic of the exanthemata, and (3) the rashes of the post-acute or post-eruptive stage. There might be a certain amount of overlapping, but, broadly speaking, the rashes were found at these stages. Except in the case of small-pox the prodromal rashes were common to certain infectious diseases, and some of the prodromal rashes even of small-pox were common to other diseases. In the exanthemata the rashes of the eruptive stage were confined to each disease; the rash of scarlet fever did not replace that of measles, for instance, but these rashes might be produced by other causes.

With regard to the post-eruptive, post-acute stage rashes, these had also been termed "secondary" or "accidental" rashes. They occurred usually from one to four weeks from the beginning of the attack. They were common to all the infectious diseases with which he was acquainted and were either urticaria, macular and slightly papular erythema, or erythema marginatum. Although they were met with in all the infectious diseases they were relatively infrequent in each one of them. He thought that it would be granted at the present day that the cutaneous eruptions, whether special or common, of the infective diseases were not primary lesions, but were only one of many changes, visible or invisible, including more or less the whole body. The chief argument in support of this statement was the undoubted fact that a person might suffer from an attack, a serious attack, of most of the acute infectious exanthematous diseases without the presence of any exanthem whatever. The next question which arose was whether the skin lesion was due to changes in the structure or alteration in the functions of any particular internal organ. So far as he was aware, there was no evidence in favour of this view. It was a question of a general cell or tissue disorder. For many years past a great deal of work had been done on the question of infection. It would appear, however, that cutaneous eruptions of the erythematous class were not visible on the skin of the animals used for experiments. Indeed, it seemed to be difficult to affect most animals with the human infectious diseases, at any rate, in the same form as they assumed in man. Included in work which he mentioned was the experimental work on anaphylaxis and the clinical work on serum sickness. Nothing occurred in animals, however, which corresponded with ordinary serum sickness in man. He emphasised the fact that the rashes of serum sickness were always either urticaria, a morbilliform erythema, or erythema marginatum.

The question which he wished to discuss was whether the phenomena of serum sickness in man or of the anaphylactic rashes in animals threw any light upon the nature of an attack of an acute infectious disease in the human subject, and he wished to discuss the question chiefly in respect of the skin eruptions. There were some who held that an attack of an acute infectious disease was an anaphylactic reaction, and they would argue, in most instances, that an attack of serum sickness was also an anaphylactic reaction. In his opinion, this was not true of an attack of an acute infectious disease, nor was an attack of acute infectious disease brought about in the same way as an attack of serum sickness. He thought that observers had been led away by the presence of the latent period in both anaphylaxis and serum sickness, and of the rashes in the latter disease. This latent period happened to be of about the same length as the incubation period of certain of the acute infections, notably measles, small-pox, chicken-pox, enteric, and typhus. In other infections, however, it was much shorter, of only one to three or four days' duration, as in scarlet fever, diphtheria, and influenza. He had stated that the rash of serum sickness was always one of three rashes. If an attack of an acute infectious disease was of the same nature as serum sickness, and still more so if serum sickness was anaphylactic, these three rashes, or one or two of them, ought to be a leading symptom in an infectious disease. But it was notorious that the rashes of the exanthemata were different one from the other, that specific rashes were entirely absent from some of the acute infections, and that they might also be absent from not a few cases of the exanthemata themselves. Inasmuch as the same rashes occurred in the anaphylactic forms of serum sickness as occurred in the ordinary form, it might be concluded that the occurrence of the rash was evidence of protein poisoning. Experiments on animals led to the conclusion that in the same animal different proteins gave rise to the same anaphylactic symptoms. Therefore he concluded that the rashes of the acute exanthemata were not due to protein poisoning pure and simple. Whatever explanation might be offered of the means by which the symptoms of an attack of an acute infectious disease was brought about, that explanation must take into consideration account the special symptoms—for example, the specific rashes. It was generally admitted that the hypothetical anaphylatoxin that produced the lesions and symptoms of anaphylaxis was a protein-cleavage product, and he was prepared to admit that such a product was the cause of the symptoms of serum sickness. Serum sickness was a comparatively *simple illness compared with an attack of an* acute infectious disease. When bacteria entered the body and became disintegrated by the action of the defensive chemistry there might be liberation of the special toxins with *later* the formation of a protein-cleavage product (anaphylatoxin). The initial and specific symptoms, including the prodromal rashes and the specific rashes, were due to the action of the special toxin. It was a fact that secondary rashes were, like the serum rashes, always either urticaria, a *morbilliform* erythema, or erythema marginatum. He suggested that they represented the reaction to the anaphylatoxin. It might be asked how was this true for the infections diseases in which the bacteria do not invade the organisms but only their toxins, as diphtheria. He drew attention to what might happen after the injection of such a poison as novarsenobillon, a non-protein poison. It had been shown that an illness closely resembling serum sickness might occur 8 to 10 days after the first injection of the *drug.* The suggestion was that the drug (or toxin, in the case of a bacterial disease) acted on the proteins of the body in such a way as directly or indirectly to lead to the formation of a protein-cleavage product. In the post-acute stage of diphtheria, untreated with antitoxic serum, rashes, quite indistinguishable from serum rashes, were occasionally met with. His conclusion was that the symptoms of an attack of an acute infectious disease were due to two main causes—the special toxin and the protein-cleavage product common *to all* (anaphylatoxin). In some infections there were no very specific symptoms—for instance, in pyæmia and septicæmia—due to streptococci. Even in these diseases rashes were not infrequently met with, so-called septic rashes. They again were almost invariably erythema multiforme or erythema marginatum, with a predilection for the extremities, and especially their extensor surfaces. There were certain experimental and clinical reasons for supposing that within limits different *proteins* produced different symptoms. Dr. Gairdner Davidson had suggested that the three different serum rashes were each due to a particular protein—albumin, euglobulin, or pseudo-globulin, the three proteins of horse serum. The subject required further investigation. Even if this proved to be the case it would not militate against the general conclusion that the rashes of the acute infectious diseases were due to special changes produced by special toxins, and that the common changes were produced by a *common toxin.*

Dr. E. GRAHAM LITTLE said that the very title of the paper indicated a refreshing break away from the arid tradition chiefly due to the German school of dermatology with its important exponent, Hebra.

Hebra's view was very uncompromisingly expressed in his chapter on diagnosis, where he wrote: "For the recognition of a disease of the skin no other assistance is required than a knowledge of the objective *symptoms which* are visible on the body in each particular case. We do not attach any value whatever either to the history or to the subjective phenomena in investigating a cutaneous affection, for we ought to be guided in this matter only by those symptoms which are appreciable by the sight, the touch, or sometimes by the smell. These afford certain and infallible grounds for the establishment of a diagnosis, for they have their origin in the malady itself."

With this conception the views of Brocq, and the French school generally, were in the sharpest conflict; it was a real satisfaction to him to hear the much more philosophic conception of the French school supported so wholeheartedly. Brocq classified skin conditions in two great groups, one containing diseases which might be regarded as true entities, of which the parasitic were the leading type, and the other, a larger group which were envisaged as skin reactions conditioned by a variety of internal factors.

The modern conceptions of the *erythema group* had their origin in the work of a general physician, the late Sir William Osler. Attention was increasingly directed to hidden foci of sepsis, the teeth and the tonsils being regarded as especially suspect, but other foci should also be considered. He could recall a very persistent and baffling case of recurrent erythematous eruption which was, in the end, definitely proved to be occasioned by a septic cyst in the appendix, the removal of which brought about a complete cessation of the eruption. In the rare and formidable condition known as disseminated lupus erythematosus all the symptoms pointed to a systemic infection, the nature of which had hitherto eluded us. He was reluctant to accept a tuberculous causation of this disease, chiefly because of its excessive rarity in young children. In a large department for skin diseases in children he had never met with a single instance during 25 years, yet the statistics of the hospital showed that fully one-third of all the admissions were due to tuberculosis. As regards a streptococcal causation, he had recently had an opportunity of observing a very severe case with *Dr. W. H. Willcox, and their attention* was especially directed to tracing a streptococcus as a causative agent, but without success. Erythema nodosum was of particular interest, for recent investigation, especially by American workers, seemed to point strongly to an infective causation, and there were at least three candidates for this bacteriological rôle: (1) the diphtheroid organism demonstrated by Rosenow in 1915; (2) the tubercle bacillus; (3) a streptococcus. He had very seldom seen any *evidence to support* the view *held* by Stokes, for merging erythema nodosum with the tuberculides, and the apparent immunity conferred by an attack, the very curious sex differentiation, and again the infrequency in childhood, made this explanation difficult to accept.

In connexion with skin vessels he spoke of the "skin-capillary microscope," invented by Otfreid Muller, of Tübingen, by the aid of which the tissues of the skin were said to become visible to the level of the subpapillary plexus. Several German authors working with this instrument admitted that their researches went a long way to corroborate the older French theories of "diatheses."

He had recently seen a puzzling case of *herpes zoster* in a man of 60. Quite definite herpes zoster on the left side was accompanied by a very remarkable eruption, which had appeared simultaneously, of sporadic vesicles exactly like the herpetic lesions, but distributed very generally over the body and especially on the trunk. There were over 280 of these vesicles. It seemed possible that this was an instance of the association between herpes zoster and varicella, which had been a burning subject of late. His opinion of the case was that it was an instance of the so-called aberrant vesicles which were seen in herpes, but never, as far as he knew, in such abundance. There were neither fever nor constitutional illness of any degree, nor were there other cases of varicella in the house or family either before or after.

Dr. H. W. BARBER, *speaking of lupus erythematosus,* said that from a series of cases collected during the past two years strong evidence was obtained that a chronic infection by a *Streptococcus longus* was the most important factor in the causation. A certain number of patients with the disease showed the stigmata, which pointed to a massive tuberculous infection in early life, and cases had been published in which it was accompanied by active phthisis or even general tuberculosis. In none of his own cases had there been evidence of active tubercle.

Recently post-mortem results of two cases had been published by Cranston Low and Rutherford. In one there were old tuberculous foci but no evidence of active tuberculosis; in the other there was complete absence of any trace of tubercle. In both there was some evidence of acute infection with a *Streptococcus longus*, in one case from the mouth and bronchi, in the other probably from the tonsils. In all his own cases one or more septic foci had been present, from which a long chained streptococcus had always been obtained, sometimes in pure culture. Primary foci would seem to be usually, if not always, the teeth, the tonsils, and perhaps the nose and nasal sinuses;

the intestines and probably the lymph glands seemed to become secondary foci in long-standing cases. In a few cases, in which oral sepsis could be excluded, the tonsils were not considered septic at first examination; further examination, however, showed the presence of pent-up pus, and after enucleation they were found to be extremely septic. It was often very difficult to decide whether the tonsils were septic or not from clinical examination.

There was a close association between lupus erythematosus and rheumatoid arthritis. He had recently seen two cases of severe rheumatoid arthritis with lupus erythematosus, and a considerable number of his own cases of lupus erythematosus had shown definite rheumatoid changes in the joints, or complaint had been made of joint pains. In the acute form these two diseases might subside without leaving any trace; in the chronic form fibrotic changes occurred which led to scarring of the skin and deformity of the joints. With regard to the association of rheumatoid arthritis and streptococcal infection of the teeth and tonsils he instanced Mollison's series of cases of improvement or cure after tonsillectomy. Acute exacerbations of lupus erythematosus in chronic cases of the disease, with the development of widespread areas of erythema resembling erythema multiforme, and accompanied by pyrexia and joint pains, were often followed, after the subsidence of acute symptoms, by rapid involution of the chronic patches.

Speaking of the results of treatment, he said that early cases had recovered completely after the removal of septic foci. Chronic cases had shown gradual but progressive improvement after removal of foci and subsequent autogenous streptococcal vaccination, and some would probably eventually recover. In some cases the vaccine had caused so much local and general reaction that it had been discontinued, and a vaccine in which the organisms were killed at 70° C. was used instead, with promising results so far. Prognosis, as with rheumatoid arthritis, depended upon the length of time the eruption had been present. Removal of septic foci in early cases might suffice to cure; in chronic cases secondary infection of the intestines and lymphatic glands probably kept the disease active.

He had recently seen some cases of young people in which there was an association of *nævi with cirrhosis of the liver*. Three were girls under 20, and on the faces of all three there was an intense acneiform eruption accompanied by rosacea, together with numerous spider nævi. Nævi were also present elsewhere—e.g., on the arms. The appearance produced by the acneiform eruption and nævi was so striking that after seeing the first case it was possible to diagnose hepatic cirrhosis in the other two at a glance. Two of the girls died with ascites, and post-mortem examination revealed extensive cirrhosis. The fourth case was a small child of a few years old who had multiple spider nævi on the face, which were steadily increasing in number, and the liver was found to be very large.

Dr. H. G. ADAMSON said that at one period all skin eruptions were looked upon as the result of some general bodily disorder. They were regarded as the outward sign of some dyscrasia or diathesis. This idea still lingered in the popular view that all skin eruptions were eczemas due either to gout or to impurity of the blood. Even at the present time most medical men were inclined to attribute skin eruptions to some internal complaint, whereas the more we knew of them the more did we find that they were ascribable to purely external causes. Scabies and ringworm of the scalp were at no very distant date thought to be the result of some internal disorder. Many forms of eczema were now shown to be the result of external irritants, as in the various occupation eczemas, dermatitis due to hair-dyes, poisonous plants, &c. A quite recent example of this change of view was the recognition of the eczematoid ringworms of the extremities. The history of dermatology during the past 100 years was that of a continuous fight against this prejudice of attributing skin diseases to a hypothetical bodily disturbance.

The more accurately skin lesions had become described, the more clearly had a large number of distinct clinical types been recognised, each of which represented a distinct form of inflammatory reaction to some one specific harmful agent. Examples were the eruptions—i.e., the types of inflammatory reaction due to the staphylococcus, the streptococcus, the acne bacillus, the tubercle bacillus, the *Spirochæta pallida*, the various forms of mould fungus, actinomycosis, sporotrichosis, even to different varieties of ringworm fungus, and to different drugs and plants and chemical agents, each of which eruption was easily recognisable by the trained observer. Again, the eruption of the specific fevers were examples of characteristic reactions to specific microbes and were familiar to all. This being so, it seemed only reasonable to suppose that in the case of eruptions of unknown origin, each with its own distinctive features, we should look for a specific agent as the cause of each. It was not suggested that all these eruptions of unknown origin were due to external agents and that none of them bore any relation to internal disorders, for we knew that there were cases in which the eruption was due to a microbe brought to the skin by the blood stream, as in syphilis, some forms of lupus, and the specific fevers. But in such cases the eruption was not the result of the bodily illness, but a part of the complaint, in which the skin eruption represented an inflammatory reaction to the same microbes as caused the internal disorder. There was a third class of eruption due to a toxin brought to the skin by the blood stream and comprising the toxic erythemas, and dermatites of toxic origin. The term "toxic eruption" had been used for serum rashes, food rashes, and even drug rashes, after its first application to cases of generalised erythema reported after injections of old tuberculin and the use of antidiphtheritic serum. The idea had led to the suggestion that many eruptions of unknown origin, such as psoriasis, pemphigus, and lupus erythematosus, were caused by toxins the result of defective metabolism, toxins absorbed from the intestine, toxins due to altered internal gland secretion or the result of absorption from septic foci. Moreover, the conception of toxic dermatitis had led to the suggestion that eruptions due to general infections or general toxæmias were to be explained as phenomena of anaphylaxis or hypersensitiveness. Thus the eruptions of syphilis or the exanthemata might be regarded as cuti-reactions in a hypersensitised subject. Similarly, in the case of horse serum, foods, or drugs their eruptions might often be produced by minute quantities of the serum, food, or drug to which the patient had become hypersensitive. This acquired hypersensitiveness possibly helped to explain why the causes of many skin affections still eluded us, for the amount of toxin required to produce the eruption might be so minute as to be detected with difficulty.

What knowledge we had taught us to look for some one specific poison for each different type of eruption, and not to be content with a general hypothesis of endogenous toxins, altered internal gland secretion, or toxins from a septic focus. As an illustration erythema multiforme might be cited. We should expect to find the causative agent of this very characteristic eruption in some one specific microbe or toxin, which was responsible both for the internal symptoms and for the eruption on the skin. Epidemics of erythema multiforme and of Henoch's purpura occurred, together with similar symptoms, and it seemed possible that these two complaints were one disease due to the same causative agent.

There were few internal disorders which we could associate definitely with a skin eruption in the relation of cause and effect. Xanthoma diabeticorum, the pigmentation of Addison's disease, and some instances of alopecia and leucoderma associated with Graves's disease were all that could be named apart from such affections as herpes zoster, which seemed to be directly dependent upon organic nerve lesions. Although it was possible that other unexplained eruptions might be shown to be due to endogenous toxins from altered metabolism associated with visceral disease, this was, at present, merely a plausible hypothesis.

Dr. J. M. H. MACLEOD said that it seemed to him that just as the skin was an important and essential organ of the body, linked up directly or indirectly in its perfect functioning with every other organ, so any diseased condition of an organ, if it went on long enough, was liable to be associated with a disorder of the skin; and, on the other hand, any diseased condition of the skin, however local its ætiology, was liable to be influenced more or less profoundly by the general internal state. He would confine his remarks to the group of cutaneous affections in which a causal connexion could usually be established with some form of alimentary toxæmia—namely, urticaria and the so-called toxic erythemata, including the group known since Hebra's time as erythema multiforme.

Gastro-intestinal derangements resulting from improper diet had been blamed by certain observers as potent influences in the causation of eczema, and in certain quarters excessive meat-eating had been held to be responsible for the aggravation of psoriasis. These views were now no longer accepted. In infantile eczema it was rare to find the association of the skin affection with digestive disturbances sufficient to cause definite symptoms, such as vomiting and diarrhœa, and he did not remember ever having met with a primary attack of eczema in an adult which followed directly on a gastro-intestinal derangement. Urticarias and erythema multiforme were not now regarded as distinct diseases, but were looked upon as cutaneous reactions due to a variety of toxic irritants, and often associated with visceral disturbances, pain in the joints and muscles, coated tongue, fever, and other evidences of a general toxæmia.

In urticaria an attack might follow the ingestion of some article of food which was poisoned, or of some food in itself innocuous but acting harmfully owing to an individual susceptibility or to an inflamed state of the gastro-intestinal tract. It was frequently observed in connexion with chronic recurrent urticaria that the primary attack was the result of some gross error in diet, while subsequent attacks resulted from an acquired susceptibility, and were produced by small quantities of the same food or of some other usually harmless article of diet. This anaphylactic phenomenon suggested that the poisonous food substance called forth a response on the part of the organism with the production of antibodies for that special food, so that after a time a second dose, even minute in quantity, was so rapidly disintegrated by the antibodies that toxic heterogenous proteins were formed which caused the cutaneous lesions. These foreign proteins were as subtle as they were virulent, and so far had escaped detection in the blood. In some cases the antibodies themselves might become absorbed, and be responsible for the cutaneous lesions.

The manner in which the urticarial reaction was called forth was unknown, and it was still a matter for discussion whether it was an angio-neurotic phenomenon due to irritation of the vaso-motor apparatus, either centrally or peripherally, by the toxin, or was an acute inflammatory process due to the local action of toxins on the cutaneous blood-vessels. When it was remembered that toxic substances, such as morphine and peptone, could produce urticaria when injected into the skin of a dog even after division of the sympathetic nerve to the part or the removal of the sympathetic ganglion, the latter explanation seemed the more probable. It was corroborated also by the observation that the fluid in a wheal was rich in albumin and more in the nature of an inflammatory exudate than a simple transudation of serum such as might occur in an angio-neurotic process. That there was some other factor there could be no doubt, as the inflammatory basis alone was insufficient to explain factitious urticaria.

The lesions of the toxic erythema group were also symptomatic of a general toxæmia, and seemed to result from the action of some toxin on the cutaneous blood-vessels. It was difficult to explain why a certain food toxin might cause urticaria in one person and an erythematous or bullous lesion in another. It might be said that food toxins of a protein nature tended to cause reactions of an urticarial or erythematous type, while bacterial toxins were more liable to give rise to bullous or purpuric lesions.

The work which had been done recently in protein sensitisation, chiefly in America, might eventually throw light on this difficult subject. In the meantime, it seemed to him that our greatest hope lay along the line of physiological chemistry, with the discovery of toxic substances in the blood, which up to now had eluded detection.

Dr. H. MACCORMAC spoke of the external parasitic or exogenous eruptions, and pointed out that internal order or disorder had a definite relationship to these local infections.

It was well known that ringworm of the scalp ceased at puberty, although at this time we could detect no microscopical, chemical, or physical change in the hair or its surroundings. Nevertheless, some extraordinary alteration must have occurred in consequence of the establishment of certain internal secretions, which might be inhibitory, as in this case, or have an effect in the causation of the disease, as in acne vulgaris, which begins about puberty. From the pustules of acne could be obtained a staphylococcus, and in some cases almost dramatic results might be obtained in acne from the use of staphylococcal vaccines, but here the infection only has been notified. On the other hand, in bromide acne the infection was secondary, and depended upon preparation for it by a previous alteration of the tissues. As pointed out by Sabouraud, the masculine type of baldness was a condition which depended upon the different functions of sex, but it also depended upon local disease of the scalp, and could be modified by treatment. These observations supplied further evidence of a general or determining element in apparently local disease.

Referring to another general factor capable of influencing local cutaneous infections Dr. MacCormac said that the frequency of scurvy among the Eskimos was well known, but it was not so generally known that they were also liable to another deficiency disease called "kallak." This occurred in epidemics, and was characterised by intense itching, and by the appearances of pustules on the hands, elbows, buttocks, and other parts. It appeared when there was insufficient fresh seal-meat, or when the herring crop failed, and was cured when these foods were freely obtained; it was thought to be due to the lack of some fat-soluble vitamine, a belief supported by known facts.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PATHOLOGY.

EXHIBITION OF SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 15th, Dr. J. C. G. LEDINGHAM, Vice-President, being in the chair.

Dr. MACKENZIE WALLIS gave a demonstration on Estimation of Sugar in the Blood.

Dr. A. E. GOW showed a specimen from a case of

Infective Endocarditis Complicated by Fat Necrosis.

The patient from whom this specimen was obtained was a distiller's carman, aged 37, who was admitted to hospital in June, 1920, suffering from subacute bacterial endocarditis.

The infecting organism was a minute Gram-negative bacillus, which was obtained on only two occasions by blood culture, and then under aerobic conditions in broth. All attempts to induce it to grow in subculture on solid media made by Dr. Gordon Mervyn and himself were unsuccessful. The organism was found in large numbers in films of the valvular vegetations post mortem. The leucocyte count was between 4000 and 5000 per c.mm. As is commonly seen in cases of infective endocarditis, the urinary output, except towards the end, was relatively high, averaging between 1600 and 2000 c.cm. in the 24 hours, and there was a remarkable constancy of the specific gravity of the 24-hour specimen of urine, which was independent of the quantity of urine passed. Albumin was always present, varying from a "faint trace" up to 0·225 per cent. (Esbach). Blood, except for one period of three weeks' duration, was practically a constant constituent of the urine, often in quantity sufficient to be appreciated by the naked eye. Post mortem both kidneys showed cloudy swelling and a slight degree of embolic focal nephritis, but were not extensively "flea bitten." The left kidney contained a small subcapsular infarct of some standing. Microscopically they showed a diffuse nephritis. Many of the Bowman's capsule spaces were dilated and the epithelium covering the tufts was swollen and proliferating and there was some adhesive glomerulitis with peri- and intra-glomerular fibrosis. Some glomeruli were transformed into fibrous hyaline masses. There were small areas of round-celled infiltration in the stroma of the cortex, the cells being chiefly plasma cells and lymphocytes. The smaller arteries showed marked arterio-sclerotic change.

Infarcts occurred in the skin, spleen, and kidney. (*a*) The skin: On admission, six weeks after the onset of symptoms, a few small purpuric spots were scattered about the body; in addition a maculo-papular erythematous rash was present on legs and trunk, being most marked on the front of the legs. On the abdomen both fading and fresh macules were present; this rash was of short duration and did not recur. No fresh petechial hæmorrhages were observed for nearly a month, when a crop appeared on the right side of the abdomen and back; after an interval of two months there was a fresh shower. During the last three weeks of his illness fresh petechiæ were found almost daily on the legs and forearms, and a day or two before death large subcutaneous hæmorrhages occurred on both thighs. Osler nodes also formed in the fingers. (*b*) The spleen: A splenic infarct occurred 22 weeks before death. On the day in question he vomited at 6 P.M., complained of sudden sharp pain in the left flank which lasted for five minutes, followed in half an hour by a rigor and temperature of 103·6° F. The next day loud friction was heard over the spleen. At the post-mortem examination three recent infarcts were found in the spleen in addition to one old one, the latter being the largest. It was limited by a well-marked capsule, the infarcted area was appreciably depressed below the surface level of the surrounding spleen, it was yellowish in colour and almost cheesy in consistence, but there was no macroscopic calcification. Sections of this old infarct showed complete necrosis and loss of structure; the area was enclosed in a thick, fibrous capsule in which were cells laden with golden-brown pigment granules. Calcification was beginning at the margin.

Diffuse fat necrosis was found involving the subperitoneal tissue of the anterior abdominal wall, mesentery, and omentum, and the perirenal and peripancreatic fat. There was no fat necrosis in mediastium. On the lower border of the pancreas, near the head, was a small area much softer to the touch than the firm gland surrounding it. This area was dark in colour and in its neighbourhood fat necrosis was most marked, the small white opaque patches being here confluent. At the time of the autopsy this was considered to be an infarct, but histological examination showed that the gland tissue was not involved, the fat necrosis being entirely extrapancreatic. Considerable dilatation of the ducts of the gland existed, but the actual cause of the necrosis had not been determined. Fat necrosis began, Dr. Gow believed, either on the thirteenth or twelfth day before death. Attacks of vomiting, with or without abdominal pain, occurred throughout the illness; in the early stages the attacks were infrequent, lasting a day or two, but towards the end they recurred at shorter intervals. On the twelfth day before death his condition appeared much worse and he became afebrile. He vomited in the morning and in the evening began to complain of a sharp pain in the epigastrium, which was increased by coughing, and there was a rise in pulse frequency from the nineties to 110 for six hours. From then onwards he went downhill rapidly; vomiting of large quantities of fluid took place at increasingly frequent intervals—thus on the eleventh day before death he brought up 700 c.cm. in five attacks, while on the fourth and third days he vomited 15 times, producing 2525 and 5350 c.cm. respectively.

The duration of the disease was 34 weeks. There was no history of rheumatic fever or other cause of endocarditis, which was, Dr. Gow believed, unusual in cases of infection with Pfeiffer-like organisms, but he had seen another example recently of an apparently primary influenzal endocarditis. Histological examination of the aortic cusp showed marked fibrotic thickening and the cusp was traversed by numerous blood-vessels containing an excess of polynuclear cells which also infiltrated the surrounding tissues. An old vegetation was extensively calcified, making it probable that he had previously suffered from endocarditis. The heart muscle showed advanced but patchy fatty degeneration, some brown atrophy, and perivascular fibrosis. Slight, but quite definite, clubbing of the fingers was noted on admission, six weeks after the onset, but did not increase appreciably up to the time of his death.

Influenzal Meningitis of the Spinal Cord.

Dr. T. H. G. **SHORE** showed a specimen of the spinal cord of an infant who died from meningitis.

The arachnoid space was filled with purulent exudate, mingled with which were areas of hæmorrhage; these did not appear to be additional to the pus, but rather the precursors of it, the infective process spreading in the effused blood. The inner surface of the dura was involved, and at the autopsy was adherent to the underlying structures, from which it had been separated afterwards in part only. Pfeiffer's bacillus was found in the cerebro-spinal fluid before death and cultivated from it. No other organism was present. There was purulent meningitis of the brain, mainly affecting the base, with ependymitis and distension of the ventricles with pus. The immediate cause of death was probably a hæmorrhage, which was found to occupy the left lateral ventricle and to have arisen from the choroid plexus. There was some purulent exudate in both middle ears, but this contained other organisms besides Pfeiffer's bacillus. The lung and air passages showed no abnormality. The child was a male infant of 10 months, breast fed, who fell out of bed three weeks before admission to hospital; afterwards he had not been well, occasionally vomiting and refusing his food. A week before he was seen the child became apathetic, took no notice of surroundings, but had no fits or further vomiting. There was high fever and pulse-rate, with irregular and rapid respiration, slight retraction of the head, and a fine tremor of the right hand. The blood was sterile.

Dr. **SHORE** also showed

The Right Knee-joint from a Case of Hæmophilia.

Hæmorrhage was present, and even after prolonged hardening in Kaiserling's fluid much of the effused blood was in a fluid state when the joint was opened. The various pouches of the joint were filled with blood, and the articular surfaces were stained by it. The synovial membrane appeared to be somewhat thickened, but histologically there was little abnormality. The cartilage of the upper end of the tibia was somewhat discoloured to a considerable depth at one point, but it was the point of attachment of one of the crucial ligaments; a similar condition was seen on the femur. The cut sections of the condyle of the femur and of the patella showed small cavities in the cartilage, some of which contained blood-vessels. The specimens were obtained from a male child, aged 4½ years, whose three brothers were healthy; all five of the maternal uncles died from hæmophilia. The boy was known for nearly four years to have had the disease, and had been in hospital on several occasions. The case had already been reported[1] by Vines, who was able to shorten the coagulation time of his blood by inducing anaphylaxis. He was brought to hospital last June, having bitten his tongue while cracking nuts with his teeth. Horse serum had no effect upon the hæmorrhage, but it was checked by a transfusion of 50 c.cm. of his father's blood. Bleeding started, however, from the operation wound and this, though small, led to his death.

Dr. **SHORE** also exhibited a specimen showing

Retrograde Extension of Carcinoma in Lymphatics.

The specimen was one of a coil of small intestine over the surface of which were several dilated lymphatic vessels; these appeared to be filled with chylous fluid, but were in reality solid. They were in direct communication with some lymphatic glands at the origin of the mesentery, which formed part of a large mass of retro-peritoneal glands surrounding the aorta and inferior vena cava and the head of the pancreas. The situation of the primary growth was not determined with certainty, but was probably in the stomach, where were several malignant ulcers and some submucous metastases. Other secondary deposits were found in the pulmonary glands and beneath the visceral pleura. Histologically the growths were spheroidal-celled carcinomata, and a section of the wall of the intestine showed growth in the subperitoneal and submucous lymphatics as well as in the lacteal vessels of the villi. There seemed no way of explaining this condition but to suppose that the carcinoma had grown backwards against the direction of the lymph flow. The specimen was removed post mortem from a man, aged 39, who was under the care of Mr. G. E. Gask, having come to hospital with ascites and constipation of five days' duration. He had had symptoms of dyspepsia for six months, and lately some vomiting and melæna. Exploratory laparotomy revealed the presence of growth and pseudochylous ascites. He died one month after he was first seen.

Dr. E. H. **KETTLE** showed specimens of: (1) a Congenital Sacral Teratoma; (2) a Primary Chancre of a Finger following Trauma.

SECTION OF ANÆSTHETICS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 4th, with Dr. H. J. **SHIRLEY**, the President, in the chair, when a paper was communicated by Dr. S. **ROWBOTHAM** and Dr. I. **MAGILL** on

Anæsthetics in the Plastic Surgery of the Face and Jaws.

The paper was based on 3000 cases at Queen's Hospital, Sidcup. After alluding to the physical and mental peculiarities of the type of patient and to the number of times each of them generally required an anæsthetic, the authors divided the cases into those in which the anæsthetist has control of the mouth and those in which he has only the nose at his disposal. In all cases the main difficulty is that of maintaining a proper air-way. When the mandible is altogether or largely missing a long blunt instrument is employed through the mouth to hold up the base of the tongue during induction. Technique was described rendering possible the use of nitrous oxide for induction in patients with broken or abnormal jaws. Intratracheal insufflation proved to be the most generally applicable method. The authors had devised means for employing gas and oxygen with this method, generally combining the gases with small amounts of ether. The methods of passing the catheter through the nose and guiding it into the larynx by specially devised instruments were described. Frequently dilatation of the nares by a series of tubes was required, and often a tube was used through each nostril. The use of nitrous oxide and oxygen, with or without the aid of local infiltration, was described in connexion with superficial flap operations. The necessary steps were described for avoiding chest complications, which are to be feared owing to the length of time required by most of the operations dealt with. These averaged one and three-quarter hours and were often over three hours. In 1700 cases there had been only four instances of bronchitis and two of pneumonia.

Discussion.

Mr. H. E. G. **BOYLE** feared that the dilatation of the nose, as described, was very likely to cause bleeding. His own experience of passing nasal tubes was that although one side of the nose was usually free it frequently happened that it was almost impossible to pass a second tube through the other nostril. He believed that colonic oil-ether anæsthesia was too uncertain for the class of case discussed and also that the long unconsciousness afterwards was a drawback. His present preference for these operations was a combination of gas and oxygen and C.E. mixture.

---

[1] Quarterly Journal of Medicine, 1920.

Mr. G. **RAMSEY PHILLIPS** pointed out that a catheter passed through the nose could usually be guided into the larynx by altering the position of the patient's head, without using an instrument through the mouth.

Dr. W. J. **MCCARDIE** said that in a large experience of the kind of case dealt with by the authors he had used very simple methods. Nasal or oral intubation with "draw-over" inhalation from a mask or plain gauze had generally given good results. Nasal tubes should have a large lumen and be comparatively stiff. There were certain advantages in the use of chloroform for these cases, little oozing and quiet respiration and circulation.

Mr. L. **KIRKBY THOMAS** said that he induced with C.E. mixture from an open mask, passed a wide rubber tube down into the pharynx and packed this round with gauze and then passed the delivery catheter of a Junker's inhaler into the tube. The catheter was kept in position by pressure against a safety-pin transfixing the pharyngeal tube.

Dr. F. E. **SHIPWAY** considered intratracheal ether far superior to the older methods for these face operations. Nasal tubes frequently cause damage with considerable bleeding, and he believed that there was a risk of conveying septic infection if a catheter were passed through the nose into the trachea.

Mr. C. T. W. **HIRSCH** described a tap for allowing small portions of ether to be taken up when it is required to supplement gas and oxygen with this anæsthetic, and Mr. **ERIC GANDY** also spoke.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AN ordinary meeting of this society was held on Feb. 18th at 1, Upper Montague-street, W.C., Dr. F. E. **FREMANTLE**, M.P., the President, being in the chair.

A portrait of Professor H. R. Kenwood, C.M.G., the ex-President, was presented to the society on behalf of the Metropolitan and Home Counties Branches. Its acceptance was asked by Dr. W. M. **WILLOUGHBY**, President of the former, and Dr. J. M. **CLEMENTS**, of the latter, and accepted by Dr. **FREMANTLE**. Professor Kenwood's great services during his two years' presidency were referred to with appreciation, especially in connexion with the reconstruction of the society and the formation of the various groups into which it is now divided. This was effected under Professor Kenwood's guidance with complete success. Twenty-four new members were elected at the meeting.

An address on

International Organisation and Public Health

was delivered by Dr. G. S. **BUCHANAN**, senior medical officer to the Ministry of Health, which appears in full in the front of our present issue.

The **PRESIDENT**, in expressing the unanimous thanks of the society to Dr. Buchanan, said that the nation was greatly indebted to the lecturer for his personal work as representative of this country in the international sphere. The address reminded them that their own interests, though infinitely wider than that of most of their fellow citizens, were narrow in comparison to the broader field which he had opened up to them.

Dr. T. H. C. **STEVENSON**, superintendent of statistics, General Register Office, speaking of the difficulties in overcoming the hidden differences in the nomenclature of death statistics in various countries, said that last year's international conference in Paris was an example of "how not to do it." It was hopeless to deal with such a subject by occasional large conferences lasting only a few days, and a smaller and permanent representative body was needed for the purpose. He asked Dr. Buchanan what he thought of the 12 days' quarantine imposed at New York for three cases of typhus.

Dr. W. **PERRIN NORRIS**, chief medical officer of the Australian Commonwealth Medical Bureau in London, said they had to break down barriers and realise the interdependence of all public health administrations, great and small. Uniformity in food legislation was greatly needed, and Dr. Norris referred to the fact that Norway had adopted laws in this connexion which had had their birth in one of the Australian States. The work did not concern only infectious disease. They had to think more of positive health—the joy in life—rather than of the mere absence of disease. What was wanted in international health relationships was, in Danton's phrase, honesty! honesty! honesty!

Dr. W. M. **WILLOUGHBY**, M.O.H., Port of London, spoke appreciatively of Dr. Buchanan's paper on the hitherto misty subject of international health agreements. All such agreements were in the end educational, and it must fall to a few nations to educate the others. The British regulations of 1907 in regard to cholera, yellow fever, and plague were far ahead of the conclusions of the international conference of 1912. The Americans were now reported as doing something which was medically unthinkable—the holding up of ships for a prolonged period in dealing with something (a few cases of typhus) quite within their control and dependent on a carrier on which they could put their finger, and which was not even microscopic. The risk even was not great enough to justify such measures. In some centres there was, of course, the possibility of danger, but this was practically obviated by being known. The experts could not have been in touch with the Government. Such matters should be left to the experts and not to the diplomats.

Dr. A. H. **BYGOTT**, M.O.H., West Suffolk, regretted that there was not more travel abroad on the part of British medical graduates. He referred to the lack of uniformity in the medical examination of emigrants in various ports, and expressed the opinion that they should not be allowed to embark at their home port unless they complied with the requirements of the country of their destination. Many ports had M.O.H.'s not specially qualified for the post. The port sanitary work in London was admirably done. The hygiene of ships was very defective, and much money and trouble would be saved to the shipping companies by an efficient and better-paid medical service on ships. More might be done for the treatment of venereal diseases on shipboard, especially irrigation for gonorrhœa.

At this stage the President left, and the chair was taken by Dr. C. **SANDERS**, M.O.H., West Ham.

Dr. C. **PORTER**, M.O.H., St. Marylebone, in thanking Dr. Buchanan, remarked that in future they would have to rely more and more on the port medical officers, who were doing a fine work.

Dr. **BUCHANAN**, in reply, thanked the meeting for their reception of his address, and said that he was glad of the opportunity, which he had not previously had, of describing to a medical or wider public the preliminary work which had been done in the establishment of an international health office. In regard to epidemic diseases, there ought to be direct interchange of information between health office and health office. When it passed through non-technical officials there was a tendency to suppression of facts which frightened them, and a good deal of existing difficulties were due to that. Such channels of communication ought to be short-circuited. He agreed with the remarks which had been made on the subject of the medical examination of emigrants, and also with Dr. Willoughby's point as to the need for the education of the smaller—and in some cases of the larger—countries.

NAVAL, MILITARY, AND AIR FORCE HYGIENE GROUP.

A MEETING of this group of the Society of Medical Officers of Health was held at the house of the society, 1, Upper Montague-street, on Feb. 4th, the President, Professor H. R. **KENWOOD**, being in the chair. Amongst those present were Sir **ROBERT HILL**, Director-General of the Naval Medical Department; Sir **JOHN GOODWIN**, Director-General of the Army Medical Service; Surgeon Rear-Admiral P. W. **BASSETT-SMITH**; and Brigadier-General W. W. O. **BEVERIDGE**, Director of Hygiene, War Office.

Lieutenant-Colonel J. **ROBERTSON** was elected a Vice-President and by-laws of the group were adopted.

The PRESIDENT, in introducing Surgeon Commander R. ST. G. S. BOND, Professor of Hygiene at the Royal Naval College, Woolwich, to read his paper on

Some Recent Improvements in Hygiene of the Royal Navy,

expressed on behalf of the group appreciation at the presence of the Directors-General of the Navy and Army.

Commander BOND said he particularly welcomed the formation of this group because it offered an opportunity to air the difficulties which beset naval hygiene from time to time and to receive criticism of our methods and suggestions from members whose wide experience in the military and civil health problems greatly qualifies them to offer.

Up to 1918 coöperation in hygienic matters was practically non-existent. The Naval Medical Service as a whole was a closed box to the outside world. There was no special health service. Within recent years, however, certain inducements and facilities have been offered to selected naval medical officers to obtain public health diplomas, and amongst these the establishment of a naval health service was the most important. The lecturer indicated the administrative procedure in detail and drew attention to the coöperation which now existed between the Naval Medical Service, on the one hand, and the Ministries of Health, Air, Agriculture, Shipping, &c., the War Office, medical officers of health, port sanitary authorities, &c., on the other hand.

After speaking of the importance of the department of civil engineers in the Service in regard to naval health and sanitary arrangements, Commander Bond went on to discuss the best methods of ventilating modern warships. The chief difficulty in this respect lay in the fact that fighting efficiency was the main object in the construction of the ship, and that ships might be sent to parts of the world where there are extremes of temperature. He said that the essentials of good ventilation in a ship were (1) the circulation of a sufficiency of fresh air; (2) the distribution of such air without creating draught; and (3) the maintenance of a suitable temperature. The conditions in a modern iron ship were like those in a bottle, through the neck of which fresh air had to gain access and foul air to escape. When a ship is in action the whole difficulty of ventilation is greatly increased, as in the supply of fresh air by artificial means poisonous gases may instead be supplied. This was a matter which was to receive further and urgent consideration.

Artificial ventilation in warships was carried out by three methods: (1) the plenum system; (3) the exhaust system; and (3) a combination of these two systems. The first was used for living spaces, a natural exhaust being trusted to. Fresh air was drawn through inlets or cowls and propelled by electric fans along steel tubes for distribution in the spaces or compartments requiring ventilation. The object was to introduce fresh air at the rate of 50 cubic feet per minute per man or 3000 cubic feet per hour. With a view to avoiding draughts, metal deflectors are placed in the trunks opposite each grating in the compartments, which by adjustment give a limited flow through each grating. When deflectors are fitted to a new ship a formula is used to make the adjustment so that a limited flow of air is directed to each outlet grating and no unpleasant draught is perceptible at more than a foot away, even when 100 cubic feet of air per minute are issuing from the grating. The maintenance of a suitable temperature was obtained by passing the cold air over thermo-tanks which were merely receptacles containing tubes through which steam passed under low pressure to warm and dry the air. A by-pass was fitted, in addition, to admit of cold air in certain proportions being mixed with the heated air. A suitable temperature is regarded as from 55° to 60° F. Such an arrangement required the closest supervision. No attempt had been made in tropical climates to supply cooled air. The exhaust system was applied exclusively to those places where great heat and vapour, foul odours, or dangerous gases were generated, whilst a combination of the systems was used for medical dressing-stations and operating rooms.

It was unfortunate that the Board of Construction did not have as one of its members the medical officer on the staff of the Medical Director-General whose duties were specifically connected with hygiene and the ventilation of ships in particular. He inspected ships only on completion, when frequently his suggestions for improvement were such as to be impracticable owing to structural difficulties. Regular observations on readings of the wet- and dry-bulb thermometer in the living spaces were taken and samples of air collected in special bottles for analysis at the R.N. laboratory at Greenwich. Any degree of CO_2 from 12 parts per 10,000 upwards indicated faulty ventilation.

In regard to accommodation 200 cubit feet has been fixed as the allowance per man, and whilst no special floor or deck space was fixed the spacing between hammock hooks must not be less than 20 inches. Formerly it was 16 inches, a condition which led to much overcrowding. In the old navy the diseases most prevalent were scurvy, small-pox, and dysentery. These had been overcome. Now they were chiefly respiratory infections. Modern conditions in a man-of-war might be said to increase this liability, and thus tuberculosis was our present-day scourge. In spite of the energetic steps which have been taken the incidence of tuberculosis in the navy still remained high and was the highest cause of invaliding out of the Service, although since the war this incidence happily has showed a marked tendency to decline.

The main preventive measures were careful physical examination on entry and early diagnosis of the disease. All men in ships were now weighed once a quarter. Men showing loss of weight or a deficiency in weight were subjected to careful examination. Suspected cases were sent to the larger hospitals, where every facility for diagnosis was at hand. Actual cases are transferred to huts in the hospital grounds conducted on the lines of a sanatorium, and later the cases are invalided out of the Service on full disability for a period of treatment in their local district. A combined Service sanatorium would prove a useful institution where discharged tuberculous men might be rendered fit to engage in the business of life subsequent to their service.

Discussion.

The PRESIDENT, in thanking the lecturer for his extremely interesting paper, referred to the birth of a Naval Health Service as marking a very important development in connexion with the health of the navy. The system of ventilation adopted was a completely scientific one, and he expected that valuable results would accrue therefrom.

Sir JOHN GOODWIN, like the President, was anxious to know whether the deflectors were in any way accessible to the men, since his experience was that ventilating shafts contained anything from a pair of socks to parakeets. To his knowledge there was an increased incidence of sickness on transports as compared with warships.

Sir ROBERT HILL was able to testify that the installation of naval health officers had created a fine liaison system between medical officers of health and the navy. During the war the question of poison gas or of the admission of T.N.T. into a ventilation system had to be taken into account, and one had to consider how much artificial ventilation one dared allow during an action.

General BEVERIDGE referred to the excessive overcrowding of the American transports. They lost 1 per cent. of their men from pneumonia, and a further 1 per cent. from men landed sick from the transports. During the influenza epidemic in the winter of 1918–19 every effort had been made to introduce greater space between the men on transports. Hitherto there had been as much space allotted as they would have had in their coffins. There ought to be a 30-inch distance between men's heads, and a superficial area of 13 sq. ft. The ventilation of dead ends was a great difficulty, and the method found to be most efficient were blowers which introduced air at floor-level. The speaker referred also to the different forms of apparatus used in ventilation, such as cowls and cowl shafts, windsails, and windscoops, and considered the use of the wet- and dry-bulb thermometer not only provided practically all that was wanted as regards the state of ventilation, but produced more reliable results. Three-quarters of infectious disease were due to respiratory transmission, which was one of the strongest arguments in favour of increased accommodation.

Surgeon Rear-Admiral BASSETT-SMITH considered that tuberculosis was of more importance than syphilis, and advocated the establishment of a Service sanatorium and the thorough examination of all men such as stokers and stewards who joined the Service later in life as a rule than the ordinary ratings.

Captain TATE also spoke and Commander BOND replied briefly.

The lecture was illustrated with diagrams and apparatus was exhibited.

Major W. N. W. KENNEDY, Town Hall, Croydon, is the honorary secretary, and will be glad to receive the names of intending members and to answer any communication.

LIVERPOOL MEDICAL INSTITUTION.

AT the last meeting of the Pathological Section, with Dr. J. E. GEMMELL, the President, in the chair, Mr. ROBERT KENNON read a paper on

TUMOURS OF THE PAROTID GLAND.

The material upon which the paper was based consisted of 124 parotid tumours removed at the Royal Infirmary, together with pathological reports and slides obtained from Professor E. E. Glynn and the private collections of Mr. R. Parker, Mr. F. T. Paul, and Mr. Thelwall Thomas. On analysis of this extensive material 91 cases were found to be adenomata, 27 carcinomata, and the remaining 6 sarcomata. In 38 cases of the adenomata after-histories had been obtained; 22 were alive and well, after an average period of 11 years; another had died without recurrence seven years after operation. Five had had recurrence. The tumour appeared most frequent in females; the age at onset averaged 30 years, the age at operation 37 years, giving an average delay of seven years before surgical aid was sought. There was a history of trauma in four cases. Pathologically Mr. Kennon considered the tumour to be an adenoma with mucinous degeneration, and later with regeneration as cartilage. There was no evidence to support a branchial or endotheliomatous origin of these tumours. Recurrence was shown to be due to insemination of the field of operation with fresh cells, which were found to be most healthy on the under side of the tumour and frequently split the capsule. The recurrence was immediate in five out of nine known dates, and averaged 1½ years; the second operation took place on the average after 5·5 years' delay. In three previous cases the subjects of recurrence had remained well for over five years. No evidence was obtained that operation hastens recurrence or shortens the life of a patient. Carcinoma of two types, the spheroidal and the cube-celled, were found; 35 per cent. of these originated in simple tumours. The malignant change in a simple tumour occurs more frequently in females about the age of 40. Pain, rapid growth, early fixation, and facial paralysis characterised these tumours. Lymphatic glands were involved late. Sarcoma, round and spindle-celled varieties occurred; one case traced died five years after the onset of the disease and two years after operation. Radium had beneficial effect on certain cases of simple origin.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

SHORTNESS OF BREATH.

A MEETING of this society was held on Feb. 9th, when a discussion on this subject was opened by Dr. L. E. V. EVERY-CLAYTON, the President. He gave a brief review of the physiology of respiration, and divided the causes of shortness of breath into inhibitions of respiratory movement, occlusion of air-passages, and changes in the composition or intrapulmonary circulation of the blood. He gave examples of each group and made a number of propositions to furnish a basis for discussion.

Dr. J. R. CHARLES demonstrated and explained Professor L. S. Fridericia's apparatus for measuring the carbon-dioxide content of the alveolar air. He showed that dyspnœa was caused whenever an increase of the circulating acids, volatile or otherwise, stimulated the respiratory centre to increased effort, and instanced the air-hunger of diabetic coma and of salicylate poisoning, as well as the dyspnœa accompanying muscular effort and provoked by excess of lactic acid. He drew attention to some of the discrepancies to be observed in pulmonary disease, where a small lesion, such as an infarct, might cause more dyspnœa than was often encountered in much grosser lesions of the lung.

Professor F. H. EDGEWORTH discriminated between subjective breathlessness and quickened respiration, and instanced "Cheyne-Stokes" breathing as a condition in which the patient had little or no discomfort. In pneumonia, with a respiration-rate of 40 per minute, there might be no subjective dyspnœa, but a patient with bronchiolitis breathing at the same speed would feel very short of breath. He also alluded to hysterical quickness of breathing.

Dr. J. O. SYMES mentioned some of the conditions in which it was difficult to explain the dyspnœa present, remarking that in cases of cardiac disease without murmurs it was apt to be a prominent symptom, and that in emphysema of the lungs it was often difficult to determine whether the shortness of breath was due to the emphysema itself or to the myocardial degeneration and the obesity which so often accompanied it. He also spoke of the dyspnœa of hyperthyroidism and of mediastinal tumour.

Dr. C. F. COOMBS gave a brief account of the origin of dyspnœa in cardiac disease, speaking particularly of conditions of deficient aeration due to right heart failure, and also summarised recent work on the part played by acidosis in the causation of "cardiac asthma" and allied disorders of respiration. He pointed out that even in the presence of organic disease of the heart the nervous element had to be considered.

Dr. R. G. GORDON said that he was impressed by the part played by the endocrine glands and the autonomic nervous system in the production of dyspnœa, and instanced the effect of emotion and of adrenalin in relieving asthma.

Dr. E. H. E. STACK asked how it was that children with evidence of acidosis might nevertheless be free from dyspnœa.

Dr. CECIL CLARKE spoke of the disproportionate dyspnœa of early tuberculosis of the lung, which he thought might be due to the action of bacterial toxins, a proposition which he supported by quoting the fact that pneumococcal infection of tissues other than the lung can quicken the respiration.

Dr. J. A. NIXON described his war experience of gunshot wounds of the chest. He showed that in these the dyspnœa was not proportional to the extent of lung injured or to the bulk of intrapleural extravasation. He showed that infection of the blood within the pleural cavity quickened respiration, and also gave examples to show that displacement of the mediastinum directly, and irritation of the pleura reflexly, had great influence on the degree of dyspnœa.

Dr. H. H. CARLETON confirmed, from his experiences in the artificial induction of pneumothorax, what had been said as to the importance of the pleural reflex.

Dr. O. H. WOODCOCK gave a brief account of a case of Hysterical Dyspnœa due to a psychoneurosis.

Dr. R. C. CLARKE said he had also noted that infection of the contents of a hæmothorax quickened the respiration.

The PRESIDENT, who had from time to time guided the discussion by interpolations, briefly summed up, congratulating the society on having brought forward so much that was interesting and instructive.

LONDON HOSPITAL MEDICAL SOCIETY.—Mr. Eardley Holland will give his address on Wednesday, March 9th, not on the 10th, as previously stated, his subject being, Cæsarean Section: the Modern Operation and its Modern Indications.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM: ANNUAL CONGRESS, 1921.—The next annual congress of the society will be held on May 5th, 6th, and 7th, at the Royal Society of Medicine, 1, Wimpole-street, London, W.1. The arrangements will be as follows: On Thursday, May 5th, in the morning, the President, Mr. J. Herbert Fisher, will deliver his opening address, to be followed by a paper by Mr. Maitland Ramsay on a Case of Cyclitis associated with Swelling of the Parotid Glands. In the afternoon a discussion on the Psychology of Vision in Health and Disease will be opened by Professor C. Spearman, F.R.S., and Sir F. W. Mott, and Mr. J. H. Parsons and Sir Robert Armstrong-Jones will speak. At 5 P.M. the Bowman Lecture will be delivered by Mr. E. Treacher Collins on Changes in the Visual Organs Correlated with the Adoption of Arboreal Life and the Assumption of the Erect Posture. Members will dine together in the evening. On Friday, May 6th, the morning session will be given up to a discussion on the Treatment of Manifest Concomitant Strabismus, to be opened by Mr. C. Worth and Mr. A. J. Ballantyne, followed by Mr. E. E. Maddox and Sir Arnold Lawson. In the afternoon a visit will be paid to St. Thomas's Hospital, which will be open for inspection. A Clinical Meeting will be held and members are invited to show cases of interest. At 8.30 P.M. Lieutenant-Colonel H. Herbert will read a paper on Results of the Iris-prolapse Operation for Glaucoma. The morning of Saturday, May 7th, will be devoted to a business meeting followed by papers. The optophone will be demonstrated in the Bowman Library during the Congress. Members desirous of offering communications, which must be typewritten, or of taking part in the discussions, are requested to communicate as soon as possible with Mr. F. A. Juler, 14, Portland-place, London, W.1.

Reviews and Notices of Books.

NOUVEAU TRAITÉ DE MÉDECINE.

Edited by G. H. ROGER, F. WIDAL, and P. J. TEISSIER. Fasc. I., Maladies Infectieuses. Paris: Masson et Cie. 1920. Pp. 482. Fr.35.

THE first volume of this treatise is a comprehensive French work on systematic medicine on the lines of the English work of Allbutt and Rolleston and the American Osler and McCrae. It is published under the general editorship of Professors Roger, Widal, and Teissier, supported by an influential committee of more than one hundred savants. Twenty-one volumes are contemplated, and, as the editors state in the preface, the work is intended to replace the well-known treatise of Charcot, Bouchard, and Brissaud, published in 1891. The scope of the work can be gauged, in general terms, by the "plan" given at the beginning of Vol. I. Starting with infective and parasitic diseases, an account of which is designed to occupy the first five volumes, the plan gives summaries of the contents of volumes dealing successively with intoxications, vitamines, disorders of metabolism and of the endocrine glands, diseases of the cardio-vascular, respiratory, digestive, urinary, and nervous systems; and concludes with a volume on the muscles, bones, and joints. In some cases two or more volumes are to be devoted to one section; for example, the diseases of the alimentary tract will occupy three volumes.

In the first three paragraphs of the preface the several editors have set before the readers high ideals. They point out that a great catastrophe has turned the world upside down and placed before the minds of modern physicians all manner of new problems. They aim at utilising the lessons of war in learning the further lessons of peace, and they appeal to the nations to coördinate their efforts in a great attempt to diminish human suffering. Professor Roger opens the description of the infective diseases with a short historical introduction of the subjects of infection, contagion, and auto-inoculation, sketching the progress which has taken place in the study of these problems, from the earliest times to the modern days of Koch and Pasteur.

The chapters of the first volume deal with various diseases produced by the following organisms: streptococcus, pneumococcus, staphylococcus, *Micrococcus tetragenus*, enterococcus, the influenza bacillus of Pfeiffer, the pneumobacillus of Friedländer, *B. psittacosis*, *B. proteus*, the organisms found associated with gas gangrene, meningococcus, and gonococcus. Brief bacteriological details, morbid histology, symptoms, signs, and treatment are all clearly and concisely set forth. The section on pneumonia and the pneumococcus must, however, be singled out for special notice. This portion of the book shows all those qualities of clear thinking and crisp, concise writing which are so characteristic a sign of the best French medical work, and Dr. P. Menetrier and Dr. H. Stevenin are to be congratulated on this part of the work. The chapter on the enterococcus should also prove valuable to English readers, as it is a subject on which our English text-books are distressingly vague and brief. The illustrations throughout the book are good, and some of the coloured plates reach a very high standard. References are given in footnotes. They are too few in number for a standard work of this kind, but as far as they go they are up to date and representative.

THE CARE OF HUMAN MACHINERY.

By R. M. WILSON, M.B., Ch.B. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1921. Pp. 238. 10s. 6d.

THIS book is composed largely of material which originally appeared in the Trade Supplement of the *Times*, where the articles condensed in clear language much that appeared during the past few years in Government publications. The author draws most of his facts from reports of the Health of Munition Workers Committee, the Industrial Fatigue Research Board, the Medical Research Council, the National Service Medical Boards, and the Factory Department, though he relies upon a few other sources. Readers unacquainted with these reports will be astonished to discover the lead which this country has taken up to the present in acquiring new knowledge, but, if they desire to read further on any subject, they will regret that the book contains no bibliography to guide them to the original sources of the knowledge—an unfortunate oversight.

An irrefutable case for factory medical officers is made out in the interests of health and efficiency and of a contented personnel and improved output. A works doctor, it is held, is a form of insurance that must soon become universal. Fatigue is discussed as the great enemy of output, health, pleasure, and joy in life—an enemy that must be kept at bay by one who understands it. Its every move must be watched and studied; but Dr. Wilson points out that so far the optimum working time for industry in general has not been determined with a sufficient degree of accuracy, still less is this the case for particular processes and individuals. Evidence is drawn from army recruiting data to prove that work is to-day making many a fit man unfit because the worker and his work are not suited. The plea may be entered that each industry should organise the health and efficiency of its workers, just as Sir Allan Smith has recently suggested that it should be responsible for its own unemployment. Its interest lies that way, for the unfit worker becomes easily fatigued and irritable; he cannot give of his best. Industry must recognise that the skilled worker is always of more value than a machine, and is worth taking care of.

Lost time is discussed by Dr. Wilson as one of the diseases of industrial life, and its extent is laid bare. Labour turnover, or "lost workers," is presented as the mortality of industry—a mortality as extensive as its cost is appalling. The need for determining both, so as to enable remedies to be applied, is adequately dealt with. The chapter on Ventilation and Output is one of the best in the book; it is up-to-date and points out how human activity is affected by "weather," which, within the workshop, can be controlled by ventilation. This matter, when our margin of safety in a health sense is low, can hardly be over-estimated. Variety, however, is needed, since rhythmical changes of air are more pleasant and stimulating than a steady, even flow. The claim is made that industrial management is intimately concerned with extra-factorial life, because "an employee who comes from a clean and wholesome house, where his meals can be properly prepared, and where his leisure can be spent advantageously, is manifestly a much better investment than one whose home is situated in a slum, whose food is ill-cooked and worse served, and whose leisure belongs for the most part to the local public-house."

Other matters, such as factory lighting, safety first, first aid, noise, and industrial welfare, are also discussed; but as the book is a summary and review of work done, it hardly lends itself to further condensation. We recommend it to our readers as a first primer of interest in itself and one which may induce them to look further into subjects of the greatest economic importance to all.

PRACTICAL MEDICINE SERIES.

Vol. III.: Eye, Ear, Nose and Throat Series. Chicago: The Year-Book Publishers. 1920. Pp. 382. $1.75.

THIS is one of a series of eight volumes of abstracts of medical and surgical literature. The third volume deals with the eye, under the editorship of Dr. Casey Wood, while the sections on the ear and nose and throat are edited respectively by *Drs. A. H. Andrews* and G. E. Shambaugh. The abstracts are mostly of articles published in American journals, but include a number of English and a few continental publications. The number of papers abstracted is very large; indeed, a smaller number and a more ruthless selection would perhaps have been of advantage. Short editorial comments have been added here and there, sometimes of rather a pedagogic nature; the labour of compilation must have been great, but it has been well repaid by the production of a volume of great interest and value, and we look forward to the regular appearance of this publication in future years.

THE CEREBRO-SPINAL FLUID.

Its Physiology and Pathology. By WILLIAM BOYD, Professor of Pathology, University of Manitoba; Pathologist, Winnipeg General Hospital. London and New York: Macmillan and Co. 1920. Pp. 176. 30s.

Professor Boyd prefaces a work which divides itself naturally into two parts, a purely scientific section and one which we may regard as clinical or empirical, with these happily chosen words:—

> "Any means which will facilitate the difficult diagnosis of diseases of the central nervous system is of value, and the cerebro-spinal fluid, which bathes its deepest recesses and washes the very nerve cells and fibres themselves, is in truth a mirror which reflects every change taking place in that system."

It is impossible to view the controversial subject of intrathecal therapy without taking into account the fact that there is a circulation of the cerebro-spinal fluid taking place in definite directions. As a result of injecting solutions containing easily visible particles it has been shown that circulation takes place upwards from the spinal sac to the lower cranial chamber, while the flow from the upper cranial chamber takes place in a downward direction. Further, there can be no doubt, as the author points out, that the fluid is a definite secretion of the choroid plexus or of the choroid gland, as Mott calls it. Not only is cerebro-spinal fluid a true secretion, but it is also absorbed along definite channels, among which the arachnoid villi must be mentioned. As with other secretions, the flow of cerebro-spinal fluid can be increased considerably by the injection of certain substances, chief among which are extracts of the choroid plexus and brain tissue. It is suggested that the function of the fluid is not purely mechanical, for its composition points to a nutritive rôle.

The clinical section of the book opens with a short discussion of lumbar puncture and its occasional harmful sequelæ. The fact that general paralytics never suffer from any symptoms either during or after lumbar puncture Professor Boyd explains by the marked excess of fluid present. It would, however, be more correct to attribute it to the general wasting of the brain, and possibly also to the dense dural adhesions which, as it were, suspend the brain from the cranial vault. He lays stress on the importance of the accurate determination of the fluid pressure, and recommends the apparatus used by Cassidy and Page for clinical purposes. In the description of routine laboratory tests no mention is made of the quantitative estimation of total protein, the dilution method for the rough estimation of protein excess, the cholin test, the Boveri test, or the Berlin blue reaction. With regard to the Wassermann reaction, sufficient stress is not laid upon the varieties of technique employed, nor on the fallacies arising if fluid is kept at room temperature or becomes contaminated. It is, moreover, regrettable that the many chemical tests are not critically discussed, and also that the practical difficulties encountered are not dealt with.

In the section of the book devoted to a discussion of the pathological fluid findings in diseases involving the central nervous system, Professor Boyd mentions that there may be a pleocytosis in cases of cerebral tumour, especially when the meninges are involved. The use of the sugar content is stated to be the chief differentiating point between acute anterior poliomyelitis and tuberculous meningitis; in the latter disease it is usually normal, while Professor Boyd states that in anterior poliomyelitis it is not reduced. Many will disagree with the statement that only 30 per cent. of cases of cerebro-spinal syphilis give a positive Wassermann reaction in the fluid, and that 70 per cent. of tabetics give a positive reaction in the blood. Professor Boyd is an enthusiast on intrathecal therapy. In the therapeutic section he states that infantile convulsions may often be more quickly relieved by lumbar puncture than by any other treatment. He quotes cases of cures of tuberculous meningitis by intrathecal tuberculin injections and of pneumococcal meningitis by ethylhydrocuprein. He gives in detail the modern treatment of neurosyphilis.

This book, taken as a whole, is a pleasantly written summary of the more important aspects of our knowledge of the cerebro-spinal fluid, which will appeal less to the laboratory worker than to the general physician.

ON BONE FORMATION.

Its Relation to Tension and Pressure. By Dr. MURK JANSEN, O.B.E., Lecturer on Orthopædic Surgery in the University of Leiden (Holland). Manchester: University Press. 1921. Pp. 114. 20s.

FOR more than half a century the views of Meyer and Culmann as to the effect of pressure and tension on formation of bone have been passively taken, and, within the last 30 years, what is known as Wolff's law, which expresses the same belief in precise terms and within implied limits, has been accepted also without serious question by anatomists, who have in general let it go, so to speak, by default. Yet objections have been raised from time to time to the acceptance of this "law," and these have come largely from orthopædic clinicians who could not reconcile it with their findings in practice. This book is the most recent declaration of the unsatisfied, for Dr. Murk Jansen holds strongly that functional pressure is an important factor in bone formation, while tension has no power in this direction, and he considers it necessary to postulate other factors which—for want of a better word—may be termed "purposive." In developing his main thesis the author has, in our opinion, certainly demonstrated that tension can have little or nothing to do with bone formation. He illustrates his point with beautiful photographs of very happy sections, not confining his attention (as did Wolff) to the neck of the femur, although his demonstrations of the conditions in coxa vara are among the most striking of his evidences. We cannot say that we think all his examples or all the explanations advanced are of the same value—Albert's "radiants" from the intercondylar fossa are extremely suggestive of crucial tension and call for more convincing treatment than Dr. Jansen's if the effect of tension is to be eliminated. Again, the reader of his exposition of pressures in joints may have an occasional feeling that the author's enthusiasm leads him to make less of the points on the other side than they really deserve. But, notwithstanding these weak spots, we cannot help feeling that Dr. Jansen has presented an excellent and almost convincing argument for his side of the question, and those who are not to be convinced will at any rate derive much interest and information from his clearly written pages. The printing is large and clear, and the get-up of the book as a whole reflects credit on its producers, as well as on its author, who is to be congratulated on a courageous attempt to reform loosely-held beliefs.

ORGANIC MEDICINAL CHEMICALS, SYNTHETIC AND NATURAL.

By M. BARROWCLIFF, M.B.E., F.I.C., and FRANCIS H. CARR, C.B.E., F.I.C. London: Baillière, Tindall, and Cox. 1921. Pp. xii. + 331. 15s.

THIS is one of a series of handbooks, edited by Dr. S. Rideal, each of which is intended to give a comprehensive survey of some branch of industrial chemistry. The preparation of the volume before us has been entrusted to two chemists who are able to speak authoritatively on both the industrial and laboratory aspects of their subject, although the former naturally takes the more prominent place. Practical details are given for the preparation of all the more important medicinal organic chemicals, some account of the underlying theory being added where necessary. Numerous illustrations of chemical plant are included and the citation of literature is very complete. The British fine chemical industry earned the thanks of the nation for the manner in which it succeeded in supplying all essential synthetic chemicals during the war. The quality of these products is excellent, but the manufactures in many cases have not yet been established on a commercial basis as regards maximum yields and minimum costs of production generally. These are matters of great national importance and, as the authors point out, perfection can only be attained by zealous work on the part of those with knowledge. University-trained men are handicapped in chemical works, as a rule, by their lack of information on current industrial conditions; this book should be cordially welcomed as helping to bridge the gap between college and factory.

EINFACHES PHARMAKOLOGISCHES PRAKTIKUM FÜR MEDIZINER.

Von R. MAGNUS, Professor der Pharmakologie in Utrecht. Berlin: Verlag von Julius Springer. 1921. Mit 14 Abbildungen. Pp. 51. M.17.

THIS little book should be found useful by those who have to arrange courses of laboratory instruction in pharmacology. Directions are given for 20 sessions; 14 of these are devoted to practical exercises to be carried out by the students themselves, consisting chiefly of work on the frog and experiments illustrating some of the chemical aspects of the subject. The remaining six sessions take the form of demonstrations selected to illustrate experimental methods as applied to warm-blooded animals. The use of complicated appliances is avoided as far as possible, and the work is planned so as to make the best use of the time available. Details of all the apparatus and reagents needed are given, and the interleaving with blank pages adds to the use of the work.

PATHOLOGY.

A Text-book of Pathology. Second edition. By W. G. MCCALLUM, Professor of Pathology and Bacteriology, Johns Hopkins University, Baltimore. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 1155. 45*s.*

Aids to Pathology. Fourth edition. By HARRY CAMPBELL, M.D., B.S., F.R.C.P. London: Baillière, Tindall, and Cox. 1920. Pp. 248. 4*s.* 6*d.*

CONSIDERED only as a student's manual, Professor McCallum's text-book has obvious disadvantages. It makes no claim to being a complete work of reference; many important conditions are omitted altogether, and there is a certain lack of balance in the space allotted to several of the commoner pathological processes. Moreover, the arrangement of the subjects is unconventional, and the student who wishes to read up the pathology of any individual organ may find the information he desires scattered through the book in half a dozen different chapters. Nevertheless, the success of the work was immediate. It has been reprinted several times, and now, four years after publication, we have the second edition. The explanation, of course, is not far to seek. Professor McCallum holds definite views which he elaborates in a logical and convincing manner. The result is a work which bears on every page the stamp of the author's individuality. We feel that he is teaching from his personal experience, and the suggestion of a compilation which is so often discernible in text-books of this size is altogether lacking. In this edition certain sections have been revised or rewritten in the light of the progress of the last few years, and several new illustrations have been added, but the plan of the work remains the same.

Dr. Harry Campbell's little book would seem to have an established vogue in student circles, and we can imagine that it is a useful aid to a qualifying examination. Indeed, the very fact that it is written by a clinician enhances its value as a guide in preparation for those ordeals which are conducted without the assistance of a professional pathologist. This edition has been slightly increased in size and has been brought up to date, though here and there an old-world flavour is still discernible. It is stated, for example, that the "hobnails" of the cirrhotic liver are portions of liver substance which have been thrust out by the contraction of fibrous tissue. And the information, on page 87, that at the growing border of a sarcoma there is a great excess of small round cells which advance in all directions, absorbing the normal tissues (histolysis) in the immediate vicinity, leaves us plunged in thought.

JOURNALS.

British Journal of Ophthalmology. October to December, 1920.—The October number is occupied by the papers read at the Oxford Ophthalmological Congress last summer on Perimetric Methods and the discussion that followed. The subject has received a great impetus since the importance of small scotomata adjacent to the blind spot in the diagnosis of incipient glaucoma has been realised, and the relative advantages of various different instruments were set forth. The same subject overflows into the November number but cannot be regarded yet as closed. At least two new instruments for the purpose have been submitted to the members of the Section of Ophthalmology of the Royal Society of Medicine during the last few months.—The subject of Colour Vision is dealt with in the November issue by Dr. F. W. Edridge-Green, who returns to the charges in his controversy with Mr. J. H. Parsons, and in the next issue Sir George Berry criticises the Young-Helmholtz theory from an independent standpoint.—These numbers also contain articles by Dr. A. W. Stirling, who maintains that the axis of astigmatism tends to shift with advancing age; by Dr. J. A. Wilson on the subject of Cinematograph Eye Irritation; by Mr. M. S. Mayou and Mr. H. Neame on the injuries to the eyes of fishes by the tar-pollution of rivers; and by Mr. H. Herbert, who describes his latest operation for glaucoma, which he terms the "small flap sclerotomy."

Journal of Laryngology and Otology. February, 1921. Vol. XXXVI., No. 2.—This number contains the second and final part of a review, by Mr. Irwin Moore, of all the recorded cases, 73 in number, of angeioma of the larynx. Spontaneous hæmorrhage occurred in 12 cases, but was never fatal; of 32 cases on which intralaryngeal operations were performed bleeding was considerable or severe in 25, but was unimportant in the 7 cases treated by thyro-fissure. An article by S. H. Mygind, of Copenhagen, deals with the occurrence of head-nystagmus in human beings; this symptom, a common result of vestibular irritation in birds and some mammals, is of the greatest rarity in man, but Mygind obtained the phenomenon in 78 per cent. of infants between the ages of one and eight months, and considers that it disappears at a later age as a result of a reflex tendency to fixation of the head originating in the cerebellum. The new editors of this Journal are Dr. Logan Turner and Dr. J. S. Fraser, of Edinburgh, and it is now published by Messrs. Oliver and Boyd, Edinburgh.

Journal of the Royal Army Medical Corps.—In the issue for January there is an article on Anoxæmia in Acute Gas Poisoning by J. Barcroft, C.B.E., F.R.S., in which it is pointed out that the pathological condition is a more or less complete oxygen-starvation of the tissues and organs, and that this may develop in three forms—the anoxic type, where, though there is plenty of hæmoglobin, the oxygen pressure is low; the anæmic type, where there is too little effective hæmoglobin, perhaps because too much has been changed into methæmoglobin or carboxyhæmoglobin; and the stagnant type, in which the blood, indeed, may be normal, but too little is delivered to the tissues. His experiments were made on goats, which endure having blood taken by aspiration from either ventricle as required for chemical examination. The arterial blood of a goat is generally oxygenated up to 90 or 100 per cent. of saturation, while the venous blood contains only half as much. The goats were given phosgene to breathe, and became "gassed." Oxygen may be used to cure them; there is one sign, cyanosis, that calls for oxygen, and there is one clinical rule, oxygen being always valuable, and in war precious—Do not use oxygen in gas-poisoning unless the patient is cyanosed. When the oxygen pressure in the blood falls below 90 per cent., headache occurs, vision is impaired, sleep is difficult, work is impossible, and voluntary movement may kill the patient, especially sudden movement. Thus an officer, gassed, died at once when, being unexpectedly shelled, he jumped for the shelter of a dug-out. The condition, to begin with is anoxic anoxæmia, but death follows by failure of the circulation, vagus stimulation, lack of vaso-motor tone, perhaps brain failure. A goat which fought hard against anoxæmia breathed more rapidly for hours, doubling thus its pulmonary ventilation, and its venous blood became more oxygenated and redder, the circulation also becoming more rapid. This all put so much strain on the goat that after 20 hours it became exhausted, its respiration and circulation failed, its blood became black, and a condition of stagnant anoxæmia was established. The cyanosis of the early stage is plum-coloured while the systems can react; when the circulation has failed the cyanosis is grey. In either of these conditions oxygen may yet restore function. The treatment for anoxæmia is, in the first place, rest and warmth; secondly, oxygen; and, thirdly, intravenous injection of saline solution, which replaces the liquid lost in developing œdema of the lungs and re-establishes blood pressure; bleeding may also be required to reduce pressure raised on the right side of the heart.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 26, 1921.

Practice Abroad.

THE issue by the General Medical Council of a new edition of their valuable report[1] on the conditions under which medical and dental practitioners registered here may practise abroad throws light on a subject of personal interest to all practitioners who are not satisfied with the circumstances of British practice. To the man or woman who has just completed his medical studies his diploma offers the opportunity of travel and adventure in a very high degree. It is only necessary to turn to the 1921 edition of the Medical Directory, with its 334 columns of practitioners resident abroad, to see how the lure of the distant and the unfamiliar has worked in our profession. Armed with a certificate of registration from the General Medical Council one may go all over the world without further formality. British Dominions and Crown Colonies, with slight exception, admit the registered diplomate to practise without further examination. This immense freedom is equally open to those who have obtained the high qualifications demanded by the registering bodies in Australia, Canada, Ceylon, Hong Kong, India, Malta, Newfoundland, New Zealand, and Straits Settlements, and whose names appear in the Colonial List at the end of the Medical Register. It is not generally known that to be inscribed on this list carries precisely the same rights and privileges as a place on the general register. Although it would require an Act of Parliament to do so, we think it would be in the best interests of medicine throughout the Empire were this list merged in the main register. Beyond this, medical practice is fenced about with an ever-increasing wall of additional examinations and other formalities. The several States of North America have not yet been able to agree on the degree of reciprocity among themselves, much less with their English-speaking brethren; repetition of all or any of the series of qualifying examinations may be required of the candidate. There are now two foreign countries, Italy and Japan, which reciprocate with us in the sense that our duly qualified practitioners can practise there and theirs here, without let or hindrance. Reciprocity with Belgium, which was found to be a useful war measure, lapsed at the end of last year without, of course, penalising those who had already taken advantage of it.

Going further afield into actually foreign lands it may perhaps be inquired why the Englishman should desire to practise in any country other than his own and among the subjects of other nationality; should he desire so to do, it is perhaps reasonable for him to be forced to obtain the same familiarity with the habits, manners, customs, superstitions, and diseases of the country as a native would do during his ordinary course of medical study. The matter is quite otherwise if his intention is to practise solely among his fellow-countrymen. France and Switzerland are, however, unwilling to allow a foreigner to treat his own countrymen resident or visiting in their country unless he has obtained what amounts to a very difficult supplementary qualification. In Switzerland we gather that the penalty for a first infringement of this rule is a heavy fine, and on repetition of the offence a similar fine, with expulsion from the country. It would not merely be a friendly act, but could hardly fail to turn to the advantage of any country to allow other nationals resident within its borders to be cared for by medical men and women of their own nationality. Even pre-war Germany made no difficulty in this regard, and English and Americans visiting Nauheim or Langelschwalbach could freely consult English or American doctors. It might be seemly for an English colony in a foreign resort to advertise for and appoint its own medical adviser. A classified list of registered practitioners resident abroad, affords material from which the relative popularity of the various localities may be gauged. In general it may be fair to assume that the number of names recorded for any district or country is the quotient of the desirability of practice in that country divided by the difficulties imposed upon the would-be practitioner.

For instance, the General Medical Council reports no restrictions on practice in Abyssinia or in the Cayman Islands, while in Siam there are no laws whatever relating to the practice of medicine or dentistry; but there are apparently few practitioners in these parts. On the other hand, the attractions of practice in Switzerland and certain parts of France and Spain are undoubtedly very great, while the number of British diplomates practising there is strikingly small. In France, although the restrictions were temporarily waived for certain practitioners during the war—it is common knowledge that a large part of civilian practice behind the war zones in France was at one time in the hands of English or Americans—examinations must be passed in French and in the same subjects as are required of French students; in Switzerland even the matriculation examination itself must be taken, an exploit which involves intimate knowledge of all high-school subjects in one of the languages current in Central Europe. The number of names in a classified local list would become smaller still on minute analysis, for some are those of British diplomates who reside abroad without the right or intention to practise there, and others are of foreigners who have had the enterprise to round off their own qualifications with the diploma of the Conjoint Examining Board. The actual position of British practice on the mainland of Europe in the year just preceding the war may be best assessed by a study of the classified list of members of the Continental Anglo-American Medical Society, which was founded in 1889 to serve as a bond of union between the British and American practitioners established on the Continent of Europe and in Northern Africa, and of which Dr. ROBERT TURNER of Paris latterly was honorary secretary. We hope to see a revival of this useful fraternity.

The Ætiology of Encephalitis Lethargica.

THE interest, mingled with alarm, felt by the general public in the new and strange malady, first described by VON ECONOMO[1] and now universally called encephalitis lethargica, or popularly "sleepy sickness," is reflected in our daily press in the shape of frequent paragraphs and articles on the subject. Official notes and statistics, issued by the Ministry of Health, have served to allay the alarm of the timid and apprehensive and have indicated to the general public that investigations into the cause of the disease are proceeding here and abroad. Bacteriologists in this country, in America, and in France have now settled definitely that encephalitis lethargica is due to a filtrable virus and that the disease is communicable to the rabbit, the guinea-pig, and less easily to the monkey. In America the research has advanced rather more rapidly than here and in France. LOEWE and STRAUSS, in a number of communications in the *Journal of Infectious Diseases* and elsewhere, and recently THALHIMER in the February number of the *Archives of Neurology and Psychiatry*, have given an account of their work which is of the highest importance. Like MCINTOSH and TURNBULL in England, and LEVADITI and his collaborators in France, they have shown that intracerebral inoculations into susceptible animals of emulsions of the cerebral lesions of cases are followed by a fatal illness which resembles the human disease. They have found, also, that blood, cerebro-spinal fluid, Berkefeld filtrates of nasal washings and filtrates of emulsions of the naso-pharyngeal mucous membrane removed at necropsy, all contain the virus. Further, they have cultivated the virus in ascitic fluid containing fresh tissue and have been able to infect rabbits with remote subcultures. The organism is described as resembling closely the "globoid bodies" recovered by FLEXNER and NOGUCHI from cases of poliomyelitis; it is a spherical body of uniform size, certainly less than 1 μ in diameter, since it passes through a filter which retains organisms of this size; it occurs singly or in pairs, sometimes in chains and groups, and is stained violet-blue by long treatment with methylene-blue and purple with Giemsa's stain. The organism is seen quite distinctly under an oil-immersion lens, and can be distinguished by its sharper outlines from the amorphous material derived from the culture-medium. Control cultures made from a wide range of material have failed to show the same organism. It appears, therefore, that the microbe of the disease has been not merely recognised, but has been cultivated.

A full account of the prolonged investigations of C. LEVADITI and P. HARVIER appears in the December issue of the *Annales de l'Institut Pasteur*. In this paper the authors deal in detail with the whole subject: the pathological anatomy of the disease as it occurs in man, and as it may be caused to occur in rabbits; the experimental study of the disease; and the bearing of the results on epidemiology and possible prophylaxis are all discussed. LEVADITI shows that the rabbit is much more susceptible to the disease than other laboratory animals. He has been able to obtain a virus fixe with which monkeys and guinea-pigs may be infected. Some of his results are not in agreement with the observations of the American authors quoted. He has not been able, for example, to recover the virus from the blood or cerebro-spinal fluid or from the naso-pharyngeal secretions; further, he has been able to infect animals only by intracranial, intra-ocular, and intratesticular injections; subcutaneous, intravenous, and intraperitoneal injections always failed. Attempts to cultivate the virus were also unsuccessful, but too much emphasis should not be laid on differences like these in work so difficult. LEVADITI and HARVIER have found a variation in virulence between different strains of the virus, and have concluded from this fact, and upon general grounds, that abortive and very mild cases occur and that probably carriers are responsible for the spread of the disease. No definite evidence has yet been obtained, however, to show that healthy persons may carry the organism. The search would naturally begin with an examination of the nasopharynx, and in this connexion some of LEVADITI'S experiments are of direct importance. He finds that the virus is unable to traverse the uninjured nasal mucous membrane of the rabbit; when, however, the mucous membrane is damaged, either by scarification or by other means, such as the application of croton oil, the applied virus is not kept back and the animal succumbs to encephalitis lethargica. The mode of spread of the disease and the mechanism of infection appear, therefore, to be the same as in epidemic poliomyelitis.

This brings us to a point of great importance which has been satisfactorily disposed of both by LEVADITI and HARVIER and by AMOSS in the current number of the *Journal of Experimental Medicine*—namely, the relationship between poliomyelitis and encephalitis lethargica. The similarities between these two diseases are obvious and have been pointed out by many writers, but there are authors who suggest also that they have a common ætiology. What this means precisely it is a little difficult to say; the phrase would require careful dissection in the light of modern work on infection. But if we take the usual meaning and assume that by "common ætiology" is meant the same causal organism, it would seem a great misfortune if such a view came to prevail without better evidence than exists at the present time. The most definite and certain facts already acquired are against such a view. The virus of poliomyelitis is very pathogenic to monkeys and practically not at all to rabbits and guinea-pigs; the reverse is the case for encephalitis lethargica. The lesions of the former disease are found in the spinal cord; of the latter, in the brain. Immunity experiments afford conclusive evidence against the view. The seasonal incidence of poliomyelitis is summer and autumn; of encephalitis lethargica, winter. These facts alone are sufficient to separate the two diseases. They both belong to the same group, however, to which may be added rabies. In all these diseases the virus is filtrable and has an elective affinity for the nervous system; their study forms one of the most fascinating branches of medical science.

The Dentists Bill.

A BILL to amend the Dentists Act, 1878, and the provisions of the Medical Act, 1886, as they affected previous legislation, was presented by Dr. ADDISON just before Christmas, and may come up for discussion in the House of Commons shortly. The object of the Bill is to prohibit the practice of dentistry by unregistered persons, and with this end in view it is proposed to constitute a Dental Board under whose administration a complete Register of the dental profession will be kept, great additions to the existing Register being made. The duty of the Board and the Registrar will be to maintain the Dentists Register, on which will be found the names of those registered under the Act of 1878, and a large body of persons who may establish a right to be admitted to the new roll. This right is defined in Clause 3 of the Act, which explains that the following persons will be included. First, all those who for five years immediately preceding the commencement of the Act have been engaged in dentistry in this country as their principal means of livelihood, or have been admitted to membership of the Incorporated Dental Society not less than one year before the commencement of the Act. Certificates of good character and of attainment to the age of 23 years will be required. Secondly, dental mechanics having similar qualifications can be admitted to the roll with the additional proviso that within two years from the commencement of the Act they must pass a prescribed examination in dental mechanics, and within ten years undergo prescribed training and examination. Thirdly, persons who within two years from the commencement of the Act pass the prescribed examination in dentistry, having been previously engaged in its practice as a principal means of livelihood. Fourthly, duly registered pharmaceutical chemists, or chemists and druggists, who can show that immediately before the commencement of the Act they had been in substantial practice as dentists and dental operators. These may be enrolled as dentists, but if they desire to practise they must give an undertaking to cease practice as chemists and druggists. Lastly, the Board can dispense with all these requirements in the case of persons whose services with His Majesty's forces have made compliance with them impossible, while it goes without saying that nothing in the Bill proposes to prevent the practice of dentistry by duly qualified medical practitioners. Dental companies are legitimised in the practice of dentistry if all the directors, managers, and operating staff are registered. It will be seen that the Bill presents many features which the qualified dentist on the present Register is sure to resent, so that it will be necessary for the Ministry of Health to defend the proposals by showing clearly where the public interest lies.

DONATIONS AND BEQUESTS.—Under the will of the late Mr. Jesse Howarth, of Manchester, the testator bequeaths to the Victoria University of Manchester £30,000 for the extension of the Jesse Howarth building of the Manchester Museum, and £15,000 to Henshaw's Blind Asylum, Old Trafford. The testator during his lifetime transferred to the Public Trustee £25,000 for the Manchester and Salford Hospital Sunday Fund. After the above and other deductions the residue of the estate, which amounted to £288,237 net, is given in trust for such charitable institutions or objects as the trustees shall direct.

Annotations.

"Ne quid nimis."

THE COLLECTIVE VOICE OF MEDICINE.

ADDRESSING sundry deputations last November Dr. Addison complained of the number of bodies that approached him claiming to be representative of the medical profession, and asked to be referred to some one body competent to speak on matters of policy affecting the profession as a whole. The supplement to the last issue of the *British Medical Journal* contains a memorandum in which it is stated that the Association has invited certain medical bodies to coöperate with it in constituting a body to satisfy the requirements of the Minister of Health. This body is to represent and be responsible to its constituents alone; it is to be concerned primarily with medical politics rather than scientific matters; it is to represent the views of the medical profession alone and their interests rather than that of the community. Some of the organised bodies mentioned in the memorandum are the Society of Medical Officers of Health, the Medical Women's Federation, the Poor-law Medical Officers' Association, the Medico-Psychological Association, and the Association of Certifying Factory Surgeons. After the adhesion of these the Royal Colleges are to be formally approached.

Apropos of this memorandum the Federation of Medical and Allied Societies has itself issued a memorandum on the collective representation of medical opinion which takes up the position that no one existing body ever can represent the medical profession, while in a federation of bodies each may retain its individuality and find adequate representation of its views. Formerly there were numerous bodies interested in the political aspects of medical and allied practice. Now, owing to the efforts of the Federation, this number has been greatly reduced, and while the Federation does not claim to be the body to represent the medical profession, it does claim to be a necessary and valuable contribution to the constitution of such a body. Confusion cannot occur between public and domestic interests, as the Federation exists only to guide public opinion, and is remote from the internal affairs of its constituents. Many medical questions having collateral interests involving the dental, pharmaceutical, or nursing professions, representatives of these are included in the Federation to make their views readily available in forming a collective opinion on broad principles of health administration.

Collective medical opinion should be based on some adequate expression of the voice of medicine locally. It may be recalled that provision was made in the National Insurance Act of 1911 for the formation of local medical committees in counties, county boroughs, and other areas large enough to have a separate insurance committee. The Insurance Commissioners having satisfied themselves that such a medical committee was properly representative of the duly qualified medical practitioners in the area, it became the recognised body to be consulted by the Insurance Committee on all questions affecting the administration of medical benefit. There was a reluctance on the part of the medical profession in general to coöperate in setting up these representative committees, and as a consequence the amending Act of 1913 made allowance for committees representative of panel doctors alone, with the duty assigned to them of ascertaining the opinions and wishes of the practitioners who entered into agreement with the insurance committees for the treatment of insured persons. In any area where no local medical committee had been set up under the 1911 Act, such a panel committee might be recognised as the local medical committee for the area. Local medical committees which are thus statutory under the Insurance Acts could easily be made representative of all sections of the profession, and it is quite certain that in any new scheme of organisation the local medical committee will be a very important body. Medical organisations of whatever kind could and should influence local medical opinion through these local committees. A natural step would then be for these local committees to elect a central executive to confer with the central government. The fault fairly found against the great central organisations as they exist is that they seldom get together for the discussion of medical politics from the point of view of the public and of the profession collectively.

TREATMENT OF HYPERTROPHIED TONSILS WITH X RAYS.

SOME workers in the laboratories of the Rockefeller Institute for Medical Research (J. B. Murphy, W. D. Witherbee, S. L. Craig, R. G. Hussey, and E. Sturm) have described[1] a new method of treatment of hypertrophied tonsils. Early in the study of the effects of the X rays it was noted that lymphoid tissue was easily affected. Long exposures in animals almost completely destroyed the lymphoid tissue along with the circulating lymphocytes. This led to the use of the rays in leukæmia and for reducing enlarged spleens in other diseases. In the Rockefeller laboratories it has been shown that the lymphoid tissue is much more susceptible than the other tissues, and that the major part of it can be destroyed without appreciable damage to the latter. This in its turn suggested the use of the rays for reducing enlarged tonsils without interfering with drainage of the crypts, thus clearing up those focal infections on the connexion of which with disease in other organs so much emphasis has recently been laid. The following was the technique. The spark-gap, measured between points, was 8 in. The distance from the target to the exposed skin was 10 in. The current was 5 milliampères. The time of exposure varied from 3 to 7 minutes, according to age. A filter of 3 mm. of aluminium was used. The approximate dose was from 1 to 1¾ skin units. The patient was placed on a table so that the rays entered under the angle of the jaw and penetrated to the tonsil. The area exposed on each side was about 3 square inches, the surrounding parts being protected by heavy sheet-lead. For young children a special board was used with retaining straps. Forty-six patients of ages ranging from 3½ to 45 years were treated, all showing more or less hypertrophy of the tonsils and disease of surrounding tissues. None was treated when there was evidence of acute infection. In some cases there were deep crypts, a ragged surface, and purulent, muco-purulent, or cheesy exudation. In all but four cases marked improvement in the tonsils followed. In the majority two weeks after the exposure distinct shrinkage was noted, and this continued for one to two months. During this period of atrophy the crypts opened and drained, and in all but a few the exudation disappeared and the surface of the tonsils became smooth, pale, and healthy. Excepting 4 cases, no exudation could be forced out at the end of the period of observation. Later examination showed the edges of the crypts to be inverted, and in a number of cases white bands like scar-tissue were seen on the surface. Other lymphoid deposits in the throat, commonly small nodules on the pillars of the fauces and masses posterior to the pillars, disappeared. Some of the patients suffered also from large masses of adenoids, for which a dose of the X rays, similar to that used for the tonsils, was given. The result was not so satisfactory, though in a number of cases decided shrinkage was noted. The inferior result was probably due to the fact that the dose received by the adenoids after passage through the bony structures of the head was small. Probably with a more suitable portal of entry better results would be obtained. An interesting bacteriological effect was that, while the common organisms of the throat were unaffected, of 36 cases showing the hæmolytic streptococcus and staphylococcus 20 became free from these organisms by the fourth week after treatment. This is attributed not to the direct action of the rays on the organisms, but to drainage of the tonsillar crypts brought about by the atrophy. In this series of cases only one patient received more than one exposure. In future cases further exposures could be given for relapse or other reason. The dose is smaller than that used in the treatment of ringworm of the scalp, the safety of which has recently been demonstrated in our columns. Further experience of the treatment is desirable to establish its position, but the results so far obtained by American workers are encouraging.

THE PICPUS QUARTER IN PARIS.

THE Picpus quarter, in which the Paris Municipal Council propose to build three new streets of tenement houses, lies between the Cours de Vincennes and the Avenue Daumesnil, in the XII. arrondissement, a somewhat sordid business district on the right bank, bordered by the Bois de Vincennes. Travellers on their way south who pass through the western corner of this arrondissement to reach the Gare de Lyon only see the comparatively modern streets. But a short distance from the Avenue Daumesnil and the rue de Lyon, which boasts a mere 74-year existence, there are almost as many links with the past to be found as in the Marais quarter. A Paris correspondent writes us the following account of the district, where demolition in the cause of health will be welcomed by the sanitarian but deplored by the archæologist.

"The name Picpus dates from Rabelaisian days and has a medical interest that may have amused the curé of Meudon. About 1550 a sudden epidemic of swellings, resembling those caused by flea-bites, covered the arms of the women and children in Paris. A monk invented an antidote in the form of a 'perfumed liqueur,' which sounds more pleasant than most of the drugs of the period, and gained for himself the sobriquet of the Père Pique Pusse. From the individual the name spread to the convent of the Reformed Penitents of the Third Order of St. Francis, and when, at the beginning of the next century Jeanne de Saulx, the widow of René de Rochechouart, Comte de Mortemart, gave the land and buildings for the monks to establish themselves in this quarter, the name Piquepusse, Picpuce, Picpus, clung to the whole locality. The story is told by all the old chroniclers of the history of Paris, but the Marquis de Rochegude, in his interesting 'Promenades dans toutes les rues de Paris' cynically remarks, 'It is more probable that this curious name of Picpus, which appeared at the end of the fifteenth century, is a corruption of the name of a householder.' At No. 61, rue de Picpus, may still be found the remains of one of the three doors of the Convent of the Third Order of St. Francis, built in 1611 on the site of a hermitage belonging to the Capuchin monks under Charles XI. Louis XIII., when he laid the foundation-stone of the chapel, gave the convent the status of a royal house, and it became the headquarters of the Franciscan Order in France. Cardinal Duperron, who persuaded Henri IV. that Paris was worth a mass, was buried in the chapel after leaving his valuable library to the monks. The present No. 42 belonged to the great Convent des Dames de Ste. Clotilde, whose property extended as far as the rue de Reuilly. The house formerly belonged to the Franciscans, and was used by the various ambassadors of the Catholic powers as a halting place before their state entry into Paris, which usually took place on a Sunday. The quarter is full of the remains of the great religious houses. Tubeuf, Anne of Austria's Finance Minister, brought from Rheims the chanoinesses of Notre-Dame-de-la-Victoire-de-Lepante, and for 150 years they celebrated every 7th of October in the buildings now numbered 37–41 the victory gained in 1572 in the Gulf of Lepanto by Don Juan of Austria over the Turks. But the most poignant memory of by-gone days is attached to No. 35, rue de Picpus, the Oratoire which served as a chapel for the convent of the nuns of the Sacred Heart of Jesus and of Mary, called the nuns of the Perpetual Adoration, the establishment described by Victor Hugo in 'Les Miserables.' At the end of the convent garden may be found the small enclosure, now called the Picpus cemetery, where were buried, heaped in a common ditch the prince and the pauper alike, the 1340 victims guillotined in 1793 on the Place du Trône-Renversé, now Place de la Nation. Among them were André Chenier, Prince Jules de Rohan, Madame de St. Amaranthe and her daughter, the Duchesse d'Ayen, the Prince de Salm Kyrburg, &c. The exact position of the ditch was indicated by a poor workgirl, Mademoiselle Paris, whose father and brother had been buried there. In 1804 the families of the victims were authorised to bury their dead in the adjoining ground and ten years later the names were engraved and the cemetery enlarged. It is owing to the fact that his wife was a daughter of the Duc d'Ayen that Lafayette was buried there.

---

[1] Journal of the American Medical Association, Jan. 22nd.

There are more cheerful souvenirs to be found in both the rue de Picpus and the rue de Reuilly. In the former Henri VI. once possessed one of his innumerable 'rendezvous de chasse' and both Ninon de Lenclos and Mademoiselle Clairon had country villas in the rue de Picpus, where ten years ago one could still see an inscription of Louis XV. on the wall at the corner of the rue Lamblardie. The rue de Reuilly goes back to Merovingian days when a royal chateau was built at 'Romiliacum.' Dagobert lived there, and married and unmarried himself with an ease that caused one old chronicler to call the place 'une sorte de harem.' On the ruins of this chateau Colbert installed a glass factory; to-day the place is occupied by an infantry barracks. Dagobert's Prime Minister, St. Eloi, is remembered in the street by the church, built on the site of his palace, that is said to contain his bones. In the Cour St. Eloi near by was the country house of the Marquise de Brinvilliers, the famous poisoner of Louis XIV.'s day. A few years ago, at No. 11, there existed a curious wine-shop called the Brasserie de l'Hortensia that is supposed to date from 1620. In 1793 it belonged to Santerre, chief of the Garde National de Paris, and it was here that the only two prisoners found in the Bastille were conducted when the fortress fell, one of them an old madman, and the other, Tavernier, a criminal, equally mad. There are many charming old-world gardens concealed by the high walls of the Picpus quarter. One of the most spacious belongs to the order of Protestant deaconnesses who for many years have conducted an excellent nursing home at No. 95, rue de Reuilly. The work they have done among the poor in the district will make them welcome the new scheme for the erection of up-to-date workmen's tenements, even if the pickaxe of the 'démolisseur' destroys some of the historical relics of the Picpus quarter."

PSEUDO-SYRINGOMYELIA AND CHRONIC POLIOMYELITIS.

AN interesting case bearing on the pathological anatomy of syringomyelia has lately been published by Dr. F. Giannuli, of the Santa Maria Asylum at Rome.[1] The patient, aged 64, was admitted for a sensory aphasia with a history that since the age of 30 he had suffered from a form of progressive muscular atrophy of the Aran-Duchenne type. When Duchenne described this form of muscular atrophy he considered it a specific entity always caused by identical lesions, but he subsequently noticed that the syndrome might result from diverse causes and not only from chronic anterior poliomyelitis. Many muscular atrophies of this type have shown symptoms of syringomyelia, some are associated with cervical pachymeningitis, others with amyotrophic lateral sclerosis, while others again are the expression of a syphilitic spinal meningomyelitis or of other pathological conditions of nerves and cord. The symptoms present in Dr. Giannuli's case were those of a classical symmetrical muscular atrophy of radicular type in the four limbs, with marked reaction of degeneration. The atrophy in the upper extremities involved also the shoulder girdle, and there were also present bilateral "main de cadavre" and symmetrical atrophy of the lower extremities with equino-varus. Tendon reflexes in the arms and patellar reflex were abolished, while the Achilles jerk was only obtained with difficulty. While there was a general diminution of sensation, the dissociated sensory disturbances of true syringomyelia were not obvious. The autopsy disclosed a form of very chronic poliomyelitis, which had lasted 40 years, characterised by a mesodermic hypertrophic inflammatory process, with hæmorrhages, extravasations, thrombi, and ischæmic medullary foci in the grey matter and secondary atrophic degeneration of the cells and nerve fibres. The ependyma of the central canal did not take part in this inflammatory process. The presence of many medullary cavities and fissures in the nerve tissue at first sight would lead to the contention that the condition was a variety of syringomyelia, but the *evident inflammatory character* of the histological processes points rather to the conclusion that it was a variety of chronic poliomyelitis. The symptoms produced by these lesions were therefore those of a progressive muscular atrophy of the Aran-Duchenne type, associated with general sensory disturbance. Dr. Giannuli considers that the presence of cavities in the medulla does not of itself constitute syringomyelia, which has a specific pathological anatomy and syndrome of its own, and that cases such as he has described should be differentiated from true or gliomatous syringomyelia to form a class of pseudo-syringomyelias, the result of very chronic poliomyelitis or sclerosing myelitic processes.

MARRIAGE OF SYPHILITIC WOMEN.

WHEN should a woman who has been infected with syphilis be allowed to marry and to bear children? The commission recently appointed by the Société Française de Dermatologie et Syphiligraphie, in reporting on the subject of marriage and syphilis, made a series of recommendations to suit varying conditions of infection, but, generally speaking, they amount to a rule that two years elapse between disappearance of all symptoms and marriage. Dr. Lacapère pointed out at the special session, when this report was considered, that a distinction had not been made between the two sexes. He considered that the general rule was too severe in the case of men, and not severe enough in the case of women. He pointed out that the commission had lent support to the generally held doctrine that congenital syphilitic symptoms are only found when the mother has been contaminated, and he believed that many debilitated children who succumb to childish infections owe their lack of resistance to an infection with the *Spirochæta pallida*, which does not cause clinical manifestations. In France—and the same is true of most European countries to-day—the war has left a large excess of females in the marriageable population. Society can therefore afford to be more stringent in enforcing celibacy on women than on men. The distinction, though not generally emphasised, has been clearly enunciated by both English and French clinicians for many years. C. F. Marshall quotes no less an authority than Jonathan Hutchinson as having said as recently as in June, 1906, "with reference to marriage, if the treatment has been continued for two years from the date of the chancre a man may safely marry, but a much longer period is necessary for a woman." Marshall himself considers that a woman should not marry within two years of the disappearance of all symptoms. H. Gougerot, the eminent French syphilologist, considers double this period to be a minimum. J. E. R. McDonagh is probably nearest the mark when he says "if a woman has had syphilis ...... however drastic the treatment has been there is always a risk that her children will be syphilitic." Syphilis in women is not often recognised in the primary stage, and once the infection has become generalised the danger of its transmissibility to the fœtus can probably never be averted. It has been shown, however, that syphilitic mothers may bear perfectly healthy children if they are properly treated with antisyphilitic remedies during the months of pregnancy, and the wisest advice a physician can give to such a woman who is bent on matrimony is that during her first and every subsequent pregnancy she must attend a venereal clinic for regular treatment and advice.

AFTER-CARE IN TUBERCULOSIS.

IN a memorandum recently issued by the Tuberculosis Group of the Society of Medical Officers of Health recommendations are made for the improvement of the tuberculosis campaign in general and after-care in particular. It is evident that this memorandum has been drawn up by persons closely in touch with the present organisation and keenly alive to its many flaws. Special attention is drawn to the need for adequate after-care, the neglect of which in the past has done so much to stultify the results of sanatorium treatment. Until after-care has been organised on thorough and comprehensive lines no satisfactory results from the tuberculosis campaign can be anticipated. The patient who returns from a sanatorium is seldom fit for whole-time work; he requires longer hours of rest and shorter hours of work than his fellows, and, as the memorandum puts it, "Suitable holidays for the tuberculous after periods of strain, such as apparently slight intercurrent illnesses, are essential to maintain them in health, and an annual holiday of three weeks is a necessity." Hitherto money has been found for sanatoriums and dispensaries, whereas little has been available for after-care and consolidation of the sanatorium "cure." Yet it is essential that the discharged patient should be subsidised for a considerable time, and re-establishment of the tuberculous as useful citizens can only be accomplished in their homes by a well-organised system of after-care. Accordingly, the memorandum recommends the establishment of an experimental local workshop in London where, under the necessary supervision, returned tuberculous persons would be employed on a part-time system, but on full wages, pending the time that they could again take their place as able-bodied workers. By this experiment much valuable information could be gained, and if the scheme proved workable vast sums, which might otherwise be expended on colonies and village settlements, could be saved. An attractive feature of this scheme is the recognition of the fact that the tuberculous, like other human beings, cling to their home surroundings and detest the uprooting which segregation in distant settlements implies. Another recommendation put forward in this memorandum concerns the administration of after-care funds. "This can only be done satisfactorily by a committee composed of persons directly interested in the welfare of the patients." The secretary to such a committee should usually be the clerk of the dispensary, who has access to most of the necessary knowledge, and Friendly Societies, trades-unions, relief organisations, local councils, boards of guardians, panel practitioners, chemists, and religious bodies of every denomination should be represented. Undoubtedly such an organisation operating in every district would soon amply justify its existence, and would do much to fill the gap at present painfully evident in the tuberculosis campaign. We commend this thoughtful memorandum to the attention of our rulers, especially in view of the Tuberculosis Bill which is likely shortly to be presented to the House of Commons for its consideration.

ACUTE ARTHRITIS IN INFANTS.

Dr. Elmer Johnson,[1] who has made a statistical study of 73 consecutive cases of acute arthritis at the Babies' Hospital, New York, remarks that invasion of the joints and periarticular tissues by pyogenic organisms is by no means rare in infants. The inflammation of the joint is usually secondary to inflammation of the epiphysis, but in many instances the inflammation spreads from the epiphysis to the periarticular tissue without affecting the joint proper. In most cases the source of infection cannot be determined. In the present series only 32 gave a history or showed evidence of a focal lesion. Pneumonia had occurred in 10 cases, umbilical infection in 4, furunculosis in 3, cerebro-spinal fever, cervical adenitis, vaginitis, ophthalmia and infected wounds in 2 each, and otitis media, scarlet fever, and breast abscess in the mother in 1 each. Forty-six of the patients were males and 27 females. The age distribution showed that the younger the child the greater was the susceptibility to purulent arthritis. Fifty-three per cent. of the series were under 6 months of age, and 74 per cent. were under 1 year. The 12 infants who were aged 1 month or under had probably been infected at birth. Though only 4 presented omphalitis on admission, Dr. Johnson suggests that bacteria may have entered the blood-stream through injuries to the mucous membrane of the mouth or by trauma from forceps. Forty-two per cent. of the children had only one joint affected, 25 per cent. had two joints affected, and 33 per cent. had more than two joints affected; 95½ per cent. of the affected joints were in the extremities. The micro-organisms causing the infection were isolated from the joints in 47 cases—namely, streptococcus in 18 cases, pneumococcus in 14, gonococcus in 7, staphylococcus in 3, *B. influenzæ* in 3, and *B. coli* and meningococcus in 1 case each. As usual, the streptococcus and gonococcus appeared to be more prone to affect multiple joints, while the pneumococcus was limited to one or two joints. Out of 19 cases in which the blood was examined the cultures proved sterile in 10, while of the 9 with a positive growth 4 showed streptococcus, 3 pneumococcus, 1 *B. influenzæ*, and 1 staphylococcus. Forty per cent. of the negative blood cultures were in children who showed no organisms in the joints, while in the positive cultures only 22 per cent. had no organisms in the lesions. In other words, there was more likely to be a positive blood culture when organisms were found in the joints. The prognosis of acute arthritis in infants is not very hopeful. Fifty-three per cent. of the present series died in hospital, 9 per cent. were discharged unimproved, and 38 per cent. were reported entirely well or greatly improved. The outlook becomes considerably better with increasing age, the high mortality among babies being mainly due to the difficulty of feeding them.

THE SPAHLINGER SERUM.

LAST week we briefly indicated the stage to which useful knowledge of the Spahlinger serum for tuberculosis had reached, concluding that it was well to await further enlightenment before passing judgment on the alleged remedy. Dr. Addison, speaking at Exeter on Feb. 18th, took occasion to correct the current report that a special medical officer of the Ministry of Health had been sent to Geneva to investigate this cure. No supply of the serum is at present available for investigation in this country, and there is nothing except statement and counter-statement on which to work. The evidence obtained from such amounts of the serum as were obtained for hospital practice was of a conflicting character and obviously excludes any claim made on behalf of the serum to be a panacea for all forms of tubercle. It is not good for any remedy, particularly a complicated remedy for a subtle disease, to be worked out in the limelight.

FATAL HÆMORRHAGE AFTER TONSILLECTOMY.

IN THE LANCET last week in the Proceedings of the Section of Laryngology of the Royal Society of Medicine, there is a report by Dr. McLeod of two cases in which death resulted from hæmorrhage following the operation of removal of the tonsils. Both patients were children, and in both death occurred within 24 hours. In the first case the sequence of events was that which is probably the usual one in these unfortunate cases: the child was apparently quite well until 4.30 in the afternoon, when she began to vomit blood; the correct procedures were taken, including suture of the faucial pillars, and left the patient improving and without bleeding, but she collapsed and died suddenly at 3 A.M. In such a case it is probable that hæmorrhage was occurring throughout the day, but the blood was swallowed and did not attract the nurse's attention; and this emphasises the importance of trying to avoid this "concealed hæmorrhage" by keeping the patient in the semi-prone position. Dr. McLeod is to be greatly commended for his courage in reporting these two cases, for fatalities due to this operation are nothing less than lamentable tragedies, and the more light thrown on their occurrence the better the prospect of their prevention. These occasional fatalities must not, however, be allowed to bias our judgment of the value of the operation, which remains an extremely safe one. In the discussion following Dr. McLeod's paper one speaker referred to five deaths in 14,700 cases, and this is probably in excess of the average, as far as deaths from hæmorrhage are concerned, for Mr. J. Milne Dickie[1] reported two deaths in 7133 operations at the Edinburgh Royal Infirmary, but neither from hæmorrhage.

AN AGREED REPORT ON VENEREAL DISEASE.

THE issue by the Birth-rate Commission of a special report[2] on venereal disease is an event of some importance. The Committee which took evidence and drew up this report included eminent medical men and women in general and special practice, with five representatives of organised religious bodies. Over this Committee the Bishop of Birmingham presided, and the Rev. James Marchant, LL.D., kept the protocol. All 19 members have put their names to a report of some 20 pages which covers both medical and moral aspects of the venereal question. Four notes of reservation, signed by individuals or groups of members, show an imperfect agreement on certain points, but what is far more striking is the unanimous statement of the case in general, which is proof positive of a far larger measure of agreement than would be gathered from a study of recent controversies. Nor has this general assent been reached by easy avoidance of controversial points, for the minutes of evidence which appear in full are absolutely frank. The National Council of Public Morals, under the auspices of which the report appears, may be congratulated on having carried through a difficult task wisely and well.

BIOLOGICAL CONTROL OF DRUGS.

THE Departmental Committee, appointed by the Minister of Health last April[3] to consider the effective control of therapeutic substances which cannot be tested by direct chemical means, has brought in its report. (In passing it may be remarked that a useful and business-like piece of work has cost the country only £182.) The witnesses examined included the President of the General Medical Council, the senior warden of the Apothecaries' Society, pharmacologists, bacteriologists, and chemists holding official position, and representatives of the firms manufacturing therapeutic products. The report is a unanimous one signed by its five members, Sir Mackenzie Chalmers (chairman), Dr. H. H. Dale, F.R.S., Mr. A. B. Maclachlan, Dr. G. F. McCleary, and Dr. C. J. Martin, F.R.S. The committee recommends that therapeutic substances which cannot be tested adequately by chemical means should be subject to supervision and control, the controlling authority to be the Lord President of the Council, the Minister of Health, the Secretary for Scotland, and the Chief Secretary for Ireland, assisted by an Advisory Committee nominated partly by these, partly by the Naval and Military Authorities, the General Medical Council and Medical Research Council, and the Pharmaceutical Society. They suggest a central laboratory under Government control, wherein standards would be prepared and maintained by which to test samples of products issued for sale, the Research Council to be responsible for this work, and the manufacturers themselves retaining responsibility for securing that their products conform with the standards laid down. Power is to be taken to inspect premises where the substances are made, whether in the United Kingdom or abroad, and to supervise the successive processes in manufacture. An appendix to the report outlines a Bill to give these recommendations legal force. A section of the daily press, which completely misinterpreted the purpose of the Committee on its appointment, has hastened to discredit the very reasonable recommendations of this report.

THE fifth report of the Joint War Finance Committee of the British Red Cross Society and the Order of St. John, just issued at the price of 1s., covers the period from Oct. 20th, 1918, to June 30th, 1920, together with a summary of the financial operations from Oct. 20th, 1914. Inasmuch as a general report on the entire war work of the Red Cross will be published in the spring, any detailed analysis is deferred until its appearance. Of the total receipts amounting to £21,885,000, the sum of £2,053,000 was paid out for the transport of wounded; £2,928,000 for hospitals, not including local expenditure on the auxiliary home hospitals; £5,017,000 for stores; £5,148,000 for prisoners of war; and £2,718,000 for post-war schemes for sick and disabled ex-Service men and kindred objects, leaving a surplus on June 30th last of £1,827,000. Claims upon this surplus on behalf of the wounded will continue for a long time, and the Joint Committee foreshadows the development of a scheme throughout the country for the benefit of disabled ex-Service men.

VENEREAL DISEASE IN THE FAR EAST.

THE Commission appointed by the National Council for Combating Venereal Diseases and sent out to the Far East under the ægis of the Colonial Office has just completed a strenuous campaign in Shanghai, where the Commission arrived early in December.

The campaign opened with a representative Conference convened by the Shanghai Municipal Council, when addresses given by Dr. Rupert Hallam and Mrs. C. Neville Rolfe received much attention. In the course of her speech Mrs. Rolfe gave a brief account of the visit of the Commission to Japan, where military examinations of all youths of 20 give some clue to the health conditions. In one province where the licensing of prostitutes was abolished 35 years ago the incidence of venereal disease was about 15 per 1000 in 1911, whereas in every other district the figures were 35 to 47 per 1000. During their brief stay in Shanghai the members of the Commission held educational conferences for heads and teaching staffs of schools, a series of medical conferences with local and visiting doctors, showed "Damaged Goods" on the film, and organised a general public meeting for foreigners resident in Shanghai. Full facilities were given for the visiting of all institutions under the control of the Municipal Council, and during the Commission's stay various hospitals, prisons, licensed quarters, and clubs were inspected. The Commissioners formulated their recommendations in a report presented to the Special Joint Session of the Municipal Watch and Health Advisory Committees. This report, which was published in the *Municipal Gazette*, urged that facilities for the free diagnosis and treatment of venereal disease should be provided by the Municipal Council; that their health and educational departments in coöperation with voluntary organisations should secure the education of the public with regard to venereal disease, and that all possible steps should be taken to suppress prostitution. It is hoped that as a result of the campaign much of the programme recommended by the Commissioners will be carried out, and that in any case the appointment of a V.D. officer and the provision of free treatment for seafarers will be considered in the immediate future.

Much interest was shown by the lay public in the aims of the Commission, and any measures instituted by the Municipal Council on the lines suggested will receive a considerable amount of local support.

MANCHESTER ROYAL INFIRMARY: X RAY AND ELECTRICAL DEPARTMENT.—A series of seven plaster models, made from X ray observations, and showing the normal stomach and the effect of posture upon its shape, have been prepared at this department and placed on exhibition in the Museum of the Royal College of Surgeons of England.

MEDICAL EDUCATION IN CHINA.

A well-attended meeting was held on Feb. 21st at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W., Sir DONALD MACALISTER presiding, to promote the advance of medical education in China.

Sir DONALD MACALISTER, in introducing Dr. Harold Balme, of the Shantung Christian University, said that he welcomed the opportunity of congratulating those who had made such wonderful progress in such a short time in medical education in China. Its future depended on the degree of support that the Western world was ready to supply.

Dr. BALME then gave his address:—

He said that prior to the beginning of the nineteenth century the study of medicine in every part of the world was hampered by the lack of a sound scientific basis, with the result that knowledge of the processes of health and of disease in the human body was the combination of many elements in which philosophy, superstition, and fantastic theory all claimed a part. The great contribution which the nineteenth century had made to the study of medicine might be described as a struggle for two dominating ideals—the determination to secure exact scientific truth in the investigation and treatment of disease, and the conception of trusteeship in relation both to medical knowledge and to the care of the sick.

We were accustomed to say that the doctrine of mandates, as at present understood, was a direct product of those newer ideas of international responsibility which had found their expression in the League of Nations. But whilst this might be true as regards the application of such a doctrine to countries, it had a much earlier birth in respect to individuals. It sprang into being on the first occasion that a physician taught that all medical discovery, and all knowledge as to the causation and treatment of disease, were the common heritage of every practitioner of medicine, and not the private monopoly of the discoverer himself. And when one began to consider what had been the results of that teaching—particularly when one viewed it against the background of countries where no such doctrine was taught—its immense effect upon the advance of medicine at once became apparent.

Visitors to China during last century again and again expressed their astonishment at the absence of any system of medical education or of hospitals, and at the lack of examinations or other restrictive qualifications safeguarding the practice of medicine. It was probably well known to all that for several centuries Chinese medical text-books had been accurately describing the symptoms of many diseases commonly met with in the country, whilst the great Chinese Pharmacopœia, compiled nearly 700 years ago, contained a number of drugs now universally used, whose action was already thoroughly understood in China at that time. But the difficulties which prevented any attempt at human dissection, and the lack of intimate acquaintance with physical science, restricted the Chinese physician to philosophic speculation and empirical observation; whilst the fact that anyone was at liberty to style himself a doctor naturally prevented the building up of a professional spirit or the development of a sense of trusteeship.

Dr. Balme then gave a historical survey of the introduction of Western medicine into China by the mission schools. Though the first voluntary hospital was opened by Thomas Colledge, a surgeon of the East India Company, in 1827, it was not till 1881 that the first Chinese medical college was established. Thereafter other small medical schools came into existence, mainly as a development of those classes for student-assistants which had been started, at first slowly and later in such numbers, in connexion with various mission hospitals. At the Biennial Conference of the China Medical Missionary Association, held in 1913, a resolution was passed urging that no further medical colleges be established until those then in existence—eight for men students and three for women students—were made efficient. And there were many who realised that even that number was beyond the power of the missions to render effective.

Meantime there came into existence a body of Chinese medical men who had received their training on modern lines, mostly in Europe and America, and who subsequently formed themselves into a National Medical Association of China. The leader of this group—Dr. Wu Lien-teh, better known in this country as Dr. G. L. Tuck—urged the Government to establish modern standards of medical education, outlining a suggested syllabus for the purpose. At the same time various of the provincial governments began to show interest in this work, and other organisations interested in the progress of China began to take a share in the work of medical education. At last, during 1914 and 1915, the Rockefeller Foundation of New York sent out two influential commissions to China, and as a result of their recommendations entered into negotiations with the London Missionary Society by which they have taken over the complete financial responsibility of the Peking Union Medical College. They are rebuilding the medical school and hospital at an expense of not far short of 2 million pounds. A large staff of expert teachers has been appointed, mostly from the United States, but also including a few men from this country; and every effort is being made to ensure that each department will be adequately equipped.

Since in this school the English language is the medium of instruction, the Council on Medical Education of the China Medical Missionary Association requested the Rockefeller Foundation to assist in the support of at least one medical school teaching in Chinese, and expressing the opinion that the school most suitable for such development was the one situated at Tsinan, the capital of Shantung province. They further urged that all missions interested in the advance of medical education, through the medium of Chinese, in the great Mandarin-speaking area of East and Central China, should concentrate their forces in the development and support of such a school. This school had now absorbed the schools at Nanking and Hankow, and the three junior classes formerly under instruction at the Union Medical College, Peking, and the Rockefeller Foundation had made a grant of over £30,000, since extended, towards the cost of additional buildings and equipment at Tsinan.

The Council of Medical Education of the China Medical Missionary Association had outlined a two-year course of pre-medical instruction, to be taken before the five-year medical course. This minimum of two years pre-medical work in the laboratory sciences was now being required at Peking, Tsinan, Changsha, and Shanghai. In this and in the extension of the curriculum of trained nurses in over 50 registered training schools to four years, China might claim to be ahead even of this country. Dr. Balme referred to the good work accomplished by the Chinese Anti-plague Bureau and to the sympathetic attitude of the Chinese Government towards the development of medical education, and concluded by explaining the financial and other difficulties confronting medical schools in China and appealing for the sympathy, encouragement, and support of the profession in this country.

Sir ALFRED PEARCE GOULD, after thanking Dr. Balme for his most interesting address, congratulated him on the excellent work he and his co-workers are doing, and proposed that the following resolution be put to the meeting:—

"Having heard with pleasure of the sympathetic interest of the Chinese Government in the development of modern medicine in China, and of the steps which have already been taken by British and American medical practitioners to coöperate with the Chinese in the establishment of medical schools in which the highest standards are set, this meeting of members of the British medical profession desires to place on record an expression of its sympathy with this effort, and its willingness to promote in every way possible the advance of medical education in China."

The resolution was seconded by Colonel W. MCADAM ECCLES and was passed unanimously.

In answer to a question by Colonel ECCLES as to how the profession in this country could give help, other than financial help, Dr. BALME said that the workers in China had great need of sympathy and of the knowledge that medical men in this country took some interest in their work. Besides financial aid, help in recruiting suitable men for posts as they became vacant was of great value. A high standard of professors was required. He asked Professor Earle, of Hong-Kong, to help him to answer this question.

Professor H. G. EARLE endorsed Dr. Balme's remarks on the stultifying effect of a sense of isolation on teachers of medicine in remote areas, and explained that the stimulus afforded by the generosity of the Rockefeller Foundation was not limited to the money received from them. For example, in Hong-Kong they had felt the stimulus though they had had no financial help, all the special buildings having been erected from money given by Chinese residents in the neighbourhood. Professor Earle considered that the most valuable help could be rendered by granting full post-graduate facilities to Chinese medical men. His advice to the Chinese student was to graduate in his own country and then to proceed to Europe or America and complete his medical education by this means.

Dr. **LOUIS SAMBON** reminded the meeting of the possible value of the ancient Chinese medical knowledge, and urged that it should be studied before it died out.

A vote of thanks to Sir Donald MacAlister, proposed by Dr. **MARY SCHARLIEB** and seconded by Sir **JOHN JORDAN**, closed the proceedings.

MEDICINE AND THE LAW.

The Assets of the Approved Societies.

Dr. Addison has made an important statement with regard to the result of the inquiry now proceeding into the assets of Approved Societies, with a view to their judicious expenditure on new forms of benefit to the contributors. From the valuations completed it can reasonably be anticipated that the total of the surplus of all the societies approved under the Health Insurance Acts will be found to exceed their liabilities by at least £8,000,000. It is proposed to treat this very satisfactory condition of things as largely due to the contributions of members insured prior to the end of 1918, and for the present, at any rate, to confine to them participation in such new benefits as their societies may decide upon. With this principle it is understood the societies generally have concurred, and they have also adopted the wise resolve not to distribute the funds at their disposal in the form of increased cash benefits. The proposals made include contribution to the funds of voluntary hospitals treating members, the provision of accommodation in suitable convalescent homes, the provision of dental and optical treatment, with the meeting of expenses arising out of these, such as the purchase of glasses. The obtaining for members of the service of nurses and of medical attendance for families and dependents was also mentioned by Dr. Addison, who rightly laid stress upon the merits of the first three suggestions enumerated above. He was able to state, moreover, that the recent raising of contributions, with an accompanying increase of benefits, had been generally accepted without opposition and acquiesced in. It is proposed that the additional benefits referred to shall begin in all societies next July, and the actuarial calculations now made should render further valuation for a similar purpose unnecessary for five years.

The Importance of X Ray Examination.

A general inspector of the Ministry of Health held recently a public inquiry into charges brought by the Norwich board of guardians against the medical officer of the Poor-law infirmary in respect of alleged lack of proper care in treating an inmate. The man had slipped and injured his leg, which became swollen and painful. An important point to be determined at the inquiry was whether there had been failure to recognise the leg as fractured by the fall and to treat it properly. There was also for consideration the question whether the patient was rightly removed to a lunatic ward, and whether the removal took place in a proper manner, having in view the fact that his leg might have been recently fractured, while the removal was effected in an ordinary carrying chair. Some conflicting medical evidence was given on these subjects. The death of the patient has taken place, and an inquest must be taken as having disposed of such issues as are indicated above. As the result of post-mortem examination medical evidence was given that there had been a fracture of the neck of the femur, but that appearances proved conclusively that this must have taken place some years before death, the recent fall having had no apparent result beyond a bruise or sprain of the hip. The medical witness stated further that deceased, in his opinion, had been properly treated. The coroner held that, so far as his duties were concerned, this made the case clear. He refused to adjourn the inquest, and found a verdict of "Death from natural causes." Apparently much trouble and anxiety to the medical man, whose professional competence was impugned, would have been spared, as well as expense to the guardians, if a recommendation of the former that an X ray apparatus should be provided for the infirmary had been accepted by the guardians.

Copeland v. Orr.

Dr. T. Orr is to be congratulated on the result of his appeal in the action for slander brought against him by Mrs. Copeland, formerly sanitary inspector and health visitor under the Ealing Town Council. The alleged defamation arose out of an unfavourable report on the plaintiff's performance of her duties made by Dr. Orr as medical officer of health at a meeting of a committee of the council. Privilege was pleaded, but Mr. Justice Roche at the trial held that there was sufficient evidence of malice to justify the case being left to the jury, who found for the plaintiff with £25 damages, for which judgment was given. The Court of Appeal has now set aside Mr. Justice Roche's judgment and entered judgment for the defendant, holding in effect that evidence that the defendant had frequently found fault personally with the plaintiff with regard to her work did not constitute evidence of malice on his part. Lord Justice Bankes pointed out that if the verdict were allowed to stand a subordinate who was censured in respect of defective work, and then reported upon to superior authority in a communication which otherwise would be held privileged, would be able to rely upon the previous fault-finding as evidence of malice.

A Massage Establishment Closed.

Mr. Chester Jones recently dismissed the appeal of Mary Frances Nolan against the refusal of the London County Council to grant her a licence to carry on a massage establishment at an address in Jermyn-street. None will question the magistrate's decision who regards massage as a form of treatment to be prescribed by a medical practitioner in suitable cases, and to be carried out according to his directions by persons who have qualified for the purpose by an adequate course of training. Establishments conducted by young women masquerading as nurses under fancy names are no doubt often sources of temptation to the immoral and of danger to persons who may enter them with no intention to indulge in immorality. The question is how to obtain evidence in cases where undesirable practices are believed to go on under the pretext of massage. In the appeal before Mr. Chester Jones at Bow-street two young men were called who were sent expressly as detectives to collect evidence, and who had gone through the process of so-called massage in a manner which they described in court. The learned magistrate expressed himself as strongly disapproving of evidence so obtained. He said in court that men who were willing, for payment, to go round to massage establishments to see whether their sexual feelings were aroused were not "very nice men," and that their evidence ought to be looked at carefully. "He did not quite understand the mentality of those who employed men on such a task." That the evidence of such witnesses, and, indeed, of all witnesses, should be scrutinised carefully none will deny. What evidence, however, would Mr. Chester Jones wish to see substituted for it? It is to be regretted that sometimes in civil life as in military matters the employment of detectives or "spies" is necessary. Persons frequenting massage establishments for immoral purposes are not likely to come forward and denounce them, and might not be believed if they did. Respectable persons lured into them are not much more likely to tender their evidence. To take an adjoining room and bore a hole through a partition or wall is generally quite impracticable. Hearsay stories might easily be obtained, but would not be received as evidence. A suggestion by the magistrate as to what he would regard as satisfactory proof of the undesirable quality of a particular establishment would have no doubt been welcomed by the London County Council.

Distributors of Cocaine.

A man calling himself Frank Simmonds, or Russell, 32 years of age, has been sent to prison for six months by Mr. d'Eyncourt, at Marylebone police-court, for having cocaine in his possession without authority. It was stated by a detective that in last September a large quantity of cocaine had been found in a flat rented the prisoner, one bottle containing 214 gr. He had arrested on Jan. 9th with a woman who next been sentenced to three months' imprisonment, but he had had to be kept in the infirmary for some time before being brought before the magistrate. The police had had great difficulty in arresting him, as he had been living at as many as 50 different addresses. The traffic done by the prisoner was in the West End. The extensive demand for cocaine in the West End of London, and the high prices obtainable for it, are to be noted in the reports of many trials. Mr. d'Eyncourt had four men before him at Marylebone in last October, charged with the same offence as Simmonds, when he sentenced two to two months' imprisonment in the second division, and bound two of them over. It is to be hoped that the longer sentence inflicted in the present case may tend to deter others, but it is evident that the high profit to be realised upon wares so easily carried and concealed render the suppression of the trade difficult. That Simmonds had money at his command can be inferred from the way in which he was able to baffle the police by changing his abode.

Since the sentence on Simmonds Carlo Ivaldi, a young Italian, has been sentenced to six months' imprisonment and deportation; he had in his possession more than 7000 grains of cocaine.

Alleged Bogus Doctor.

In THE LANCET of Feb. 5th attention was drawn to a woman calling herself Margaret Crawford (or Margaret de Lancy Williams), whose arrest was sought on a warrant by the police for alleged offences against the Medical Act, 1858. This woman was arrested in Dublin on Feb. 10th, and brought before Mr. D'Eyncourt at Marylebone police-court on Feb. 18th to answer four summonses preferred by the Medical Defence Union, Ltd., of falsely pretending to be a general medical practitioner in August and September last, and of falsely using the title of Bachelor of Medicine on three death certificates. The accused pleaded guilty and was fined £20, with 5 guineas costs, for each of the offences.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Increased Fees at Scottish Universities.

THE four Scottish Universities have had under consideration the necessity for increasing their fees in order to meet the greatly enhanced cost of services and upkeep. Draft ordinances are at present passing through their various stages in each university to enable this to be done. On Feb. 14th the General Council of Edinburgh University approved of an increase in the matriculation fee from one guinea to two guineas, and of the examination fees of from 33 to 50 per cent. It was agreed that the proposed increase should not be applied retrospectively to degree examinations which a student had already passed. An ordinance was also approved increasing the basis of assessment for the purpose of ascertaining the pensions of professors and principals. The question of superannuation of university staffs was also raised, and it was intimated that the four Universities had joined in endeavouring to have a Bill introduced giving them powers to deal with the whole problem. They hoped the measure would give power to establish an age-limit for professors and principals, and that it would enable them to homologate the professorial pensions with those of the lecturers and other members of the staff. A meeting of the University Court held the same day approved of the above draft ordinances. The Court also approved of increased fees in all the faculties, and directed that they should become operative from the commencement of the ensuing summer term.

"Carriers" of Disease.

The Scottish Board of Health have issued a circular letter to local authorities stating that they have had under consideration the spread of infectious diseases by means of "carriers" and the powers of local authorities to deal with such cases. They have accordingly, in terms of the Public Health (Scotland) Act, 1897, drawn up regulations giving the local authority power to deal with any "carrier" of infectious disease in the same manner as if he actually suffered from the disease. Before any person is to be deemed a "carrier" he must, however, be certified as such by a medical officer of health and also by another registered medical practitioner, such certificate to have effect for a period not exceeding three months. Further examinations may be made at any time, and the carrier may demand re-examination during the currency of a certificate. These regulations come into force on March 1st, 1921. The Board have also under discussion the question of special treatment in special classes of carriers, with a view to rendering restraint of the carrier unnecessary. They are also in communication with the Medical Research Council regarding the problem of enteric carriers.

Consultative Council's Scheme for a National Medical Service.

The "Scheme of Medical Service for Scotland," proposed by the Consultative Council, has met with much adverse criticism. Amongst the public objection is taken chiefly because of experience of the working of the National Health Insurance Act, and reluctance is widely expressed at extension of its "benefits" and the ignoring of the question of expense. Amongst the profession the proposal meets with opposition for the same reasons, and also because of the attitude which, it is held, is maintained towards practitioners. Many of the clauses, it is said, assume the hopeless incompetence of the general practitioner at a time when the universities and the medical corporations have raised the standard of medical education to an unprecedentedly high level. The assumption is inconsistent with the experience of medical practice before the days of the Insurance Act. If conditions have altered, State interference must be held responsible say the critics.

Edinburgh University Extensions.

The first meeting of the general committee in connexion with the extension scheme of the University, and the appeal for £500,000 to meet the cost, was held on Feb. 18th, Principal Sir Alfred Ewing, K.C.B., presiding. Letters commending the appeal were read from Mr. A. J. Balfour (Chancellor of the University), Mr. Lloyd George (Lord Rector), and Sir Henry Craik, M.P. Sir Alfred Ewing made an introductory statement, pointing out that there were essentially two sides of University finance—the question of current expenditure, which had recently increased enormously, and of capital outlay. The present appeal was to meet the latter. From time to time there came a crisis in the history of any university, when its material shell became too small for the organism inside it. Fifty years ago they had had such a crisis, with the result that the new buildings had been erected, and thanks to that the Edinburgh Medical School had maintained its proud and unique position. Another crisis was upon them again. In some departments the buildings and equipment were wholly inadequate, as there were now in the University about 5000 undergraduates compared with about 3000 in the old days. At present applications from many well qualified to undertake research had to be declined for lack of room. They were appealing not only on sentimental grounds, but also because of the practical work of recognised value which the universities could do for the country, and which could be done only by them. He hoped the universities would long retain their independent position, but they could only do so if their friends assisted them in times of need. The Chancellor of the Exchequer had said that grants would largely depend upon the efforts made by individual universities and the response to them. They were making their effort now. It was not a good time, but they were obliged to do it. He appealed not only to Edinburgh, but to the sons of the University everywhere. Intimation of subscriptions amounting to about £20,000 was made. Lord Provost Chesser and others spoke in support of the scheme, and an influential committee was appointed for its furtherance.

Feb. 21st.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Doctors as Detectives.

AN Order in the following terms has recently been served on the secretaries of the several general hospitals in Dublin:—

> To the Secretary, ... Hospital.
>
> By virtue of the powers conferred on me under *Regulation 53 of* the Restoration of Order in Ireland, Regulation 1, the undersigned, being a Competent Military Authority under the said regulations, do hereby order you, the secretary, being the person in charge of the .... hospital, to furnish to me (in writing) the names and descriptions of all persons admitted to your hospital who are or are suspected to be suffering from wounds caused by bullets, gunfire, or other explosives, together with such particulars and information concerning them as may be within your knowledge. Such information is to be furnished by you daily to me at Headquarters, Dublin District, Lower Castle Yard, Dublin. Failure to comply with this Order will render you liable to be proceeded against for an offence against the Restoration of Order in Ireland Regulations.
>
> ———, Colonel Commandant,
> Commanding Dublin District,
> Competent Military Authority,
> Lower Castle Yard, Dublin.

A similar Order was subsequently served on the medical officers of various workhouse hospitals throughout the country. As might be expected, the Order has caused a good deal of discussion among the medical men affected. It is recognised that it is the fixed ethical practice of the medical profession that a medical man is not at liberty to disclose information concerning his patient of which he has become possessed in virtue of his professional position toward the patient. It is true that he has no privilege in point of law and that if produced as a witness in court he must answer such questions as he is ordered by the judge, or be willing to be punished for contempt. The present Order goes much further than this. It does not insist that a medical man should give true and full evidence when called on, but that he should of his own motion inform the authorities of the condition of certain of his patients. It is, no doubt, the duty of all good citizens to do what they can, both to prevent crime and to aid the authorities in detecting it, but it is pointed out that one can hardly find a precedent for the imposition on medical men as a special duty that they should act as detectives in the course of their professional work. This is the view of the Order taken generally by the medical profession in Ireland. Apart from the ethical question involved, obedience to the Order would in certain areas of Ireland expose a medical man to grave danger. Up to the present, medical men have performed their professional duties in Ireland without considering any question other than the need for their services. They have attended the sick and wounded regardless of politics or nationality, and on the whole they have enjoyed a certain immunity while doing so. It would be very unfortunate if the military authorities were to press on the medical profession as a whole a line of action which would be regarded as unprofessional. Under the circumstances, I am glad to learn that certain Fellows of the Royal College of Surgeons, feeling the difficulty of their position, have sought advice and aid from the Council of the College. The Council may be trusted to make suitable representations to the military authorities, and it is to be hoped that the latter may see their way to withdraw or cancel an order which is certainly irritating to the profession and likely to be ineffective.

CITY OF LONDON AND EAST LONDON DISPENSARY.—The report and balance-sheet, which will be submitted to the annual meeting of governors of this institution at the Dispensary, 40, Wilson-street, Finsbury-square, on March 1st, shows a satisfactory year's working. The objects of the institution are to supply medical and surgical advice, with medicines, to the poor and destitute; the attendances during the year 1920 were the highest on record, being 161,616. 971 patients received gratuitous care, the others made some weekly payment. Donations and subscriptions amounted to £107 8*s*., including a sum of £22 4*s*. 6*d*. placed in the dispensary box by the patients; they may be sent to Messrs. Barclays Bank, Ltd., 54, Lombard-street, London, E.C. 3, or to the secretary of the institution, 53, Lombard-street.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Compulsory Typhoid Vaccination.

THERE is in France a movement in favour of compulsory vaccination against typhoid fever, more especially in the event of epidemics. Proposals have also been made to institute compulsory vaccination in districts where sporadic cases are frequently notified. At two of the recent meetings of the Académie de Médecine MM. A. Chauffard, C. Achard, H. Vincent, and Léon Bernard have urged the need for a campaign in this direction. Mons. Bernard recalled a previous communication in which he pointed out that by a mere decree compulsory vaccination against typhoid fever, such as that existing in the army, would be applicable to the civilian population in case of an epidemic. Mons. Bernard was of opinion that it would be difficult to determine by law the age at which such vaccination ought to take place. Mons. Chauffard proposed the age of 15, whereas Mons. Vincent was in favour of vaccination even amongst children. Finally, a committee was formed to study the questions involved, the members of which are MM. A. Chauffard, Léon Bernard, F. Widal, and H. Vincent.

Post-graduate Courses in Paris.

A course in dermatology and venereal diseases, under the direction of Professor Jeanselme, will be held in April, May, and June, beginning on April 11th, at the Hôpital Saint Louis. Lectures will be given from 1.30 to 4 P.M., and the mornings will be devoted to clinical teaching, laboratory work, &c. The fee payable will be Fr.150 for the course, and a certificate will be issued to those who have attended it. Further information may be obtained from Mons. Marcel Bloch, Chef de Laboratoire à la Faculté, Hôpital Saint Louis, 40, rue Bichat (10e), Paris.

A three months' course in electro-therapeutics, radiology, and radium-therapy will be held under the auspices of La Société des Médecins-Chefs des Laboratoires de Radiologie et d'Électro-Radiothérapie des Hôpitaux de Paris, beginning on April 11th. Lectures will be held daily at 6 P.M., and demonstrations in the mornings. The course is free to medical practitioners. Further information can be obtained from Dr. Mahar, Hôpital Trousseau, 158, Avenue du Général-Michel-Bizot, Paris (XIIe).

Modification of the Internat Competition.

There are some 300 house physicians and house surgeons, the so-called internes, on duty in the various Paris hospitals. These Internes des Hôpitaux de Paris, to give their qualification in full, are selected from senior medical students, who can attain to such a post before being registered as medical practitioners. Competitive examination takes place every year amongst those students who have already obtained by competition the grade of Externe des Hôpitaux. The "Concours de l'Internat" takes place annually in October. The candidates number a few hundred, from whom the first 60 are selected as internes and hold this post for four years. Every year each interne becomes assistant to a different chef-de-service, who may be a surgeon or a visiting physician to the same hospital or a different one. Internes are able to choose the post desired according to their precedence in classification. Candidates are asked to write a two hours' paper on anatomy and one on medicine or surgery, and are required to read their own papers before juries composed of ten surgeons and physicians. Some 200 candidates are selected from this preliminary competition and are then subjected to oral tests from which 60 emerge triumphant, being made Internes Titulaires with the privilege of becoming a resident at any of the Paris hospitals under the administration of the Assistance Publique. About 100 others are made Internes Provisoires, and are entitled to compete again the following year. A number of physicians and surgeons are of opinion that the form of the competition should be revised. It is proposed that an eliminating examination should be held in July, consisting of a paper on anatomy, and a second competition should take place in October, consisting of three papers on anatomy, medicine, and surgery. In these parts of the competition the names of the candidates would not be disclosed to the examiners. An oral competition on the lines of the second part of the present internat would complete the ordeals. Apart from this suggestion, which seems to be the most in favour, there have been other reforms suggested, but the authorities have not yet come to a definite decision on the matter.

The Budget of the Assistance Publique.

The Administration Générale de l'Assistance Publique, which involves the management of nearly all the hospitals in Paris, has been granted a budget of Fr.228,486,330 by the authorities of the Conseil Municipal de Paris, in accordance with the conclusions of the committee of management. The present chairman, known as Directeur-Général de l'Administration de l'Assistance Publique, is Mon. Louis Mourier, formerly Sous-Secrétaire d'État au Service de Santé Militaire, who succeeded Mons. G. Mesureur on his retirement in November last.

New Wing to the American Hospital in Paris.

A committee has been formed in order to deal with suggestions for improvements at the American Hospital in Paris, which is to have a new wing. The cost will amount to $400,000. There are now 32 beds in the hospital, and it is intended to increase this number to 100.

A Surgical Member of the Académie des Sciences.

The election of a surgeon to replace the late Professor F. Guyon as Membre Titulaire de l'Académie des Sciences has aroused much interest. The names of the following surgeons had been suggested: MM. Pierre Delbet, J.-L. Faure, E. Hartmann, F. Legueu, T. Tuffier, and Pierre Bazy, and it is the latter who has been selected for the honour.

Feb. 16th.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Outbreak of Exanthematic Typhus.

AN attack of typhus exanthematicus has recently occurred in the city and has not yet been suppressed. Sixteen of a party of 21 foreign artists arriving here after a tedious journey from Odessa were taken ill almost simultaneously and brought to the isolation hospital; soon afterwards another group of nine persons, also late arrivals from South-Eastern Europe, were discovered suffering from the same disease; and a few days later seven more cases were discovered. This last group also consisted of foreigners from various countries, having no connexion whatever with the first two groups of patients. Four persons have died up to date; all necessary precautions have been taken to prevent a spread of the infection. During the war the city was comparatively free from typhus; an occasional case was found amongst the soldiers, but rapid control of such small foci was always established, thanks to the excellent work of the disinfecting group of the sanitary staff. As the population is almost completely free from lice, infection hardly ever took place.

Precarious Position of General Practitioners in Vienna.

At a meeting of the Vienna Organisation of Practitioners, not intended for public notice, the critical position of a large percentage of the doctors in Vienna was discussed. Apart from a comparatively small number of specialists and surgeons, medical men can hardly contrive to earn a living. The Krankenkassen doctors have recently succeeded in forcing the insurance clubs to pay them substantially increased fees, but they have lost nearly all their private practices. The population is itself so impoverished that people cannot afford to pay the comparatively high fees of a private doctor during a long illness. The family doctor is rapidly disappearing, for his middle-class patients are forced to apply to hospitals or out-patient departments and renounce all ideas of comfort during illness. Servants are now so expensive that many doctors have to do without them, taking their meals with their families in the "war kitchens" where the food supplied is below the usually recognised standard of quality. It is impossible for the doctor to buy new clothes or keep a carriage, and an increase of the rate of fees is no longer feasible. The medical organisation is working hard to assist men whose position would otherwise be quite untenable.

The Biological Society of Vienna.

At a recent meeting of the Biological Society of Vienna the problem of the interstitial cells of the sexual glands was discussed. Professor E. Steinach's experiments led him to declare that by causing a proliferation of these cells rejuvenation of the organism can be produced in a marked degree. Professor J. Kyrle stated his opinion that the interstitial cells do not directly produce the secondary sexual symptoms, but augment the action of the specific generative cells. Steinach's operation causes a marked change in the circulation and metabolism in the testicles, thus producing an increase of the interstitial cells. Professor Steinach said that he was not the originator of the method, but that he had continued the work of other men. He showed rats and specimens of rat testicles and ovaries which had been subjected to his operation. Amongst them were four rats of one family—a normal masculine rat, a normal sister, a castrated sister, and another castrated sister in whose body a testicle had been implanted. The last had the external appearance of a powerful male rat. Histological examination of the implanted testicle showed that the specific glandular cells disappear, whilst the interstitial cells become hypertrophied. This fact, Professor Steinach maintained, shows that the appearance of male characteristics in a previously female organism is due to the interstitial cells. Professor J. Tandler remarked that the duration of the rejuvenating effect in man was still unknown, and that the results of animal experiments are not simply applicable to human physiology; therefore he was opposed to the operation on man. Professor G. Holzknecht said that the method of rejuvenation by means of X rays was in no way deleterious, as far as is known at present. In a large number of cases exposed for various reasons to Rontgen rays within the last 20 years neither in men nor women had any bad effect been observed; nor amongst the numerous physicians and X ray assistants who within the last 15 years had, no doubt, occasionally been exposed in such a way that their sexual glands were influenced had a single case of "hyper-hormonisation" been observed. The first and principal proposition of Professor Steinach—"sexual hormones are specific for the sex"—was, in the opinion of Professor Holzknecht, proved, and this was the basis of Steinach's teaching. Professor Lichtenstern said that by introducing the method of transplantation into therapeutics it had become possible to treat such hitherto refractory conditions as eunuchoidism and homosexualism. He was the first man in this country to ligate the vas deferens, not as an experiment, but from precise surgical indications. As no ill-effects were noted after the lapse of one year he carefully selected cases of precocious senility and adopted the ligation with the idea of obtaining similar results to those of the rat experiment. The cases were kept under observation for from two to two and a half years; no untoward effect had yet been observed. In females surgical castration was not adopted; massive doses of X rays were given, producing interstitial inflammation of the glandular tissue. The favourable effects noted in former years after X ray treatment of myomatous conditions of the uterus were, in Professor Lichtenstern's opinion, due to this cause.

Feb. 14th.

LITERARY INTELLIGENCE.—Messrs. Oliver and Boyd announce the early publication of the University of Edinburgh "Roll of Honour," 1914-1919, edited by Major John E. Mackenzie.—Messrs. Cassell and Co., Ltd., announce the forthcoming publication of the seventh edition of Sir Patrick Manson's "Tropical Diseases."

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

CITY OF LONDON.

OWING to the exigencies of war Dr. W. J. Howarth's annual report for 1919 is practically the first report of its kind presented by him during his seven years' tenure of office to the Lord Mayor, Aldermen, and Commons of the Corporation of London. Previous summaries have consisted of abbreviated tabulations of statistics and scant references to the work done during the year. In Dr. Howarth's view, the annual report of a medical officer of health should be a document in which not only results and records are set out, but in which this officer is able to bring to the notice of his authority the arguments for and against current proposals, and in which he is permitted reasonable latitude to state his own views thereon. An expression of opinion of this character does not necessarily commit the authority, but it furnishes members with information to enable them to consider the situation and partially to be in a position to criticise, vary, or support the policy which the medical officer of health may subsequently submit for consideration or adoption.

In the case of the City of London this requirement is as necessary as in other districts, for although the resident population has decreased to practically insignificant numbers it occupies the position of an authority which has a tradition behind it, centuries old, of interest in all matters which concern the welfare of the inhabitants of this country in general and those of its citizens in particular. If ever the Corporation were to take the view that its responsibilities were limited to safeguarding the health of the few thousands of resident inhabitants, its interest and action in public health affairs will then approach the parochial. Fortunately, there is neither indication nor danger of this state of affairs developing, for the Corporation continues to take the keenest interest not only in the night population, but in the welfare of those who return daily to the square mile which constitutes the City to earn their livelihood. It must be acceded that in many matters relating to later developments in State medicine the direct interest of the City is slight. These developments more and more emphasise the fact that the individual unit must play an important part if future improvement is to result. In this connexion the influence of the Corporation can be most effective. The very freedom of the City from direct interest enables it to give a decision on policy which is free from suspicion of ulterior motive. Its judgments become those of a body influenced only by the consideration of what is most advantageous to the many. Historical records show that from the earliest days of this country's development the City interested itself not only in public health matters but also in curative medicine and in organisations of direct professional concern. The letter-books of the Corporation, which continue to be issued at intervals, throughout their pages illustrate instances of the Aldermen and Court of Common Council exercising authority. Preventive measures adopted in the City during the plague period have proved the basis of many modern developments. Interest in the medical treatment of the poor was shown when the Corporation undertook responsibility for the administration of St. Bartholomew's Hospital in the sixteenth century, and the development of the controlling colleges of both physicians and surgeons have followed the interest which the Corporation took in the profession at the instance of members of the early guilds.

Dr. Howarth might, in our opinion, have added to this brief account of the City's activities in health matters the fact that Sir John Simon, who subsequently became medical officer to the Privy Council and Local Government Board, and who laid the foundation of our modern system of public health administration, was the first medical officer of health of the City of London, having been appointed by the Corporation in the year 1848.

Dr. Howarth's object in referring to these matters is to direct attention to what would appear to him to be the unfortunate effect of any interference with the autonomy of the Corporation which might cripple its initiative, or subordinate its authority. Whatever developments result in public health administration in London, and such are undoubtedly necessary, he is satisfied that the City may advantageously be left as a separate authority subject only to the controlling power of the Ministry of Health. We entirely agree with Dr. Howarth's contention and we hope that the Corporation of the City of London will be left to manage its own affairs, which it has always shown itself eminently capable of doing.

Dr. Howarth makes some interesting remarks on the important subject of medical treatment in general.

He points out that increased responsibility for medical treatment is being placed upon the public health authorities, and alludes to Sir George Newman's valuable report on the principles to be observed in coördinating the two great divisions of medicine—namely, preventive and curative. The first result of this report has been the reference to the Consultative Council on Medical and Allied Services under the chairmanship of Lord Dawson, "to consider and make recommendations as to the scheme or schemes requisite for the systematic provision of such forms of medical and allied services as should be available for the inhabitants of a given area." This committee has now reported to the Ministry of Health, and the resulting document is of considerable interest. It was hardly to be expected that any strikingly original idea would be put forward, and its great use lies in the fact that it has considered all existing suggestions and has selected the best elements in these, and with additions has framed an ideal scheme outlining the final organisation which should be aimed at to secure that the best medical treatment shall be available for persons requiring it. Criticism of the report is unnecessary since it suggests that it only deals with principles. On broad lines it is acceptable, but it would appear to lack the practical touch, and expense alone would prevent any attempt to put the scheme into immediate operation, though the time has now arrived when the important aspect of progressive development should be considered.

It is, of course, essential that medical treatment shall be so coördinated that the many specialised branches of treatment may form one piece of smooth running administrative machinery, but if the machinery provided is to be of the greatest service, it is equally necessary that the means which will ensure the masses availing themselves of the facilities shall also exist. Future organisation must be such that will encourage cases of early illness to come under treatment in the more certain remediable stages, and, if treatment is to be the helpmate of prevention, the medical practitioner must be educated in the fuller appreciation and the real import of early symptoms, and also in drawing conclusions from the nature of the illnesses which are observed in the group of patients for which he is responsible.

Dr. Howarth suggests that consideration should be given to the following points: What is the most practical method which will ensure that persons will seek medical treatment early, or that incipient disease will be recognised at an earlier date than is now the case? Ought the principles of National Insurance to be extended, and, if so, to what extent, and how should the cost of such extended facilities be met? How can the poor, who are now included in the Insurance scheme, be brought into a scheme of national treatment and still remain free from the stigma of pauperisation and free from risk of involvement in invidious distinctions? How can the activities, knowledge, and experience of general practitioners be best utilised in preventive work? How can existing institutions be adapted to help in the development of the system? Can existing local authorities be vested with the power of providing national treatment, and the medical profession, which is so intimately concerned in this work, be given a share of the responsibility?

Other suggestions could be introduced, but these appear to Dr. Howarth to be of the most pressing importance, and any practical scheme using existing machinery modified and extended as the circumstances seem to require, is the immediate essential. Alteration in the matter of the treatment of the indigent poor, which is at the present time undertaken by the Poor-law authorities, appears to Dr. Howarth to be premature and undesirable until the details of future development have been considered and decided upon. Variations, whatever they may be, should be on lines which will ensure that they fit in the new programme. If they do not, radical change will again be necessary in the near future. It has been suggested that the visitation of sick poor by the staff of the medical officer of health should be undertaken. This, in Dr. Howarth's opinion, would be a duty which is outside the scope of the medical officer's functions. These are mainly administrative, and, even if the proposal were put into effect as a temporary measure, there would still be the sentimental objection which attaches to charitable relief, and that objection would exist so long as an individual requiring relief is singled out for special consideration. With the extension of National Insurance it does not seem an improbable proposition to provide for the poor, as well as for those who are able to pay weekly contributions.

URBAN VITAL STATISTICS.

(Week ended Feb. 19th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 12·3, 13·1 and 14·0 in the three preceding weeks, further rose to 15·4 per 1000. In London, with a population of 4½ million persons, the death-rate was 14·2, or 1·0 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 7·5 in Wimbledon, 8·3 in East Ham, and 8·5 in Lincoln, to 22·8 in Sunderland, and 23·7 in Bournemouth and in Dewsbury. The principal epidemic diseases caused 239 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 78 from infantile diarrhœa, 65 from diphtheria, 47 from whooping-cough, 26 from measles, 21 from scarlet fever, and 2 from enteric fever. Measles caused a death-rate of 2·4 in Middlesbrough, and whooping-cough of 2·0 in Warrington. There were 3919 cases of scarlet fever and 2808 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3945 and 2770 respectively at the end of the previous week. During the week ended Feb. 12th 16 cases of encephalitis lethargica were notified in the County of London, and comprised 2 each in Hackney, Islington, Lewisham, and Stepney, and 1 each in Battersea, Finsbury, Greenwich, Hammersmith, Kensington, Poplar, St. Pancras, and Southwark. The causes of 33 of the 5488 deaths in the 96 towns were uncertified, of which 7 were registered in Birmingham, and 3 each in London and Middlesbrough.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 16·3, 14·9, and 17·4 in the three preceding weeks, rose to 18·2 per 1000. The 394 deaths in Glasgow corresponded to an annual rate of 18·7 per 1000, and included 36 from whooping-cough, 7 each from diphtheria and infantile diarrhœa, and 1 each from measles and scarlet fever. The 143 deaths in Edinburgh were equal to a rate of 16·7 per 1000, and included 5 from measles, 2 each from scarlet fever and infantile diarrhœa, and 1 each from diphtheria and whooping-cough. A fatal case of small-pox was registered in Kirkcaldy.

Irish Towns.—The 148 deaths in Dublin corresponded to an annual rate of 18·2, or 0·7 per 1000 below that recorded in the previous week, and included 2 from infantile diarrhœa and 1 from diphtheria. The 149 deaths in Belfast were equal to a rate of 18·5 per 1000, and included 13 from whooping-cough and 2 from infantile diarrhœa.

Obituary.

WILLIAM ODLING, M.B. LOND., F.R.C.P. LOND., PH.D. LEYDEN, F.R.S.,

LATE WAYNFLETE PROFESSOR OF CHEMISTRY, OXFORD.

William Odling, who died at Oxford on Feb. 17th in his ninety-first year, was a well-qualified member of the medical profession, although his fame as a chemist was greater. The son of a surgeon, he was born in London in 1829, and subsequently studied medicine at Guy's Hospital, graduating M.B. at the University of London in 1851. After qualifying he went to Paris, where he became a pupil of Gerhardt, the Strassburg chemist whose influence largely determined his later studies. On his return to England he was appointed director of the chemical laboratory at Guy's Hospital, and in 1863 lecturer in the same subject at St. Bartholomew's Hospital. He became a Fellow of the Royal College of Physicians of London in 1859. In 1868 Odling was appointed Fullerian Professor of Chemistry at the Royal Institution in succession to Faraday, holding the post for four years, and succeeding Professor Benjamin Brodie in the Waynflete chair of chemistry at Oxford. Here he spent the remainder of a long life until his retirement in 1912. Odling contributed much to the literature of his specialty; it was he who suggested the use of the terms "monad," "dyad" &c., in connexion with the valencies of chemical elements. His popular exposition of chemical processes and experiments charmed the boyhood of many of the present generation. The effect of a medical training on his chemical work is shown in the attention which he devoted to such subjects as the chemistry of bread-making, the purification of rivers, and the analysis of drinking water.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—The discussion in your columns on referred pain is very interesting, especially Dr. J. A. Ryle's remarks on the variation of hyperæsthetic areas with the presence or intensity of the pain. Personally I admit I have not been sufficiently alive to this variation. In cases of ulcer of the stomach or duodenum in hospital the patients usually have been set at rest, diet regulated, and so on, by the resident staff before they come under examination before a class; then the teacher finds, accordingly, that the percentage of paræsthetic phenomena is low. The same variation applies in angina pectoris, at any rate in single consultations, as attacks may not have occurred recently. The family physician has more opportunity of observing the attacks and their epiphenomena. Time after time I have looked for them in vain, although I may have been assured by the patient or his doctor of their incidental appearance.

But this is by the way. I write more definitely to carry forward the interesting observation of the arousing or increasing of pain about an ulcer by distension of the stomach. I think none of your correspondents has quoted the experiments and conclusions of Dr. H. K. Anderson, the Master of Caius, on this side of the inquiry. I have given a fairly full account of Anderson's hypothesis in my book on "Arterial Disease." It is shortly as follows:—All sensation is cutaneous. In the course of evolution the viscera are formed by introversion, packing inwards, of the surface, so that, however involved, each viscus has still its portion of under-skin carried in with it. These portions we call the investments, or capsules, of the several viscera, such as pleura, pericardium, peritoneum, and so forth. In my book I use this hypothesis to explain certain phenomena of angina pectoris, pains that arise most frequently in the investments of the aorta. These cutaneous investments of the viscera carry with them their sensory end-organs, Pacinian bodies, &c. If this be so, and in this the histologists (Dogiel and others) are agreed, we should expect to find, as we do find, these end-organs, not in the parenchyma, but in the investment of the organ observed. It is true, therefore, that, speaking generally, the viscera are insensitive in their substance, but are sensitive, often exquisitively sensitive, in their capsules. Hence, for instance, the pain on distension of the stomach—the investment is put on the stretch. The bowel again is insensitive so long as the mesentery is not put on the stretch, but, drag on this cutaneous investment, and pain awakens. Pains, then, are referred not from the viscus but from its overcoat. Many a local disease remains painless so long as such an investment is not irritated or pulled upon. So far I venture to demur to Dr. A. F. Hurst's axiom that "the viscera themselves are sensitive" (p. 348, col. 2). The heart, let me say, is in its substance insensitive, and the pericardium is so continually subject to changes of diameter as to be less sensitive to drag than, say, the mesentery; but when the pericardium is sharply stretched beyond its mean—as, e.g., by a coronary embolism—acute pain may arise. Morphologically, then, all sensations are cutaneous in seat, whether directly visceral or referred; whether they originate in the implicated skin and end-organs—as we see profusely (say) in the mesentery, or in the investment of the aorta, and so on—or directly on that actual surface which only we are accustomed to call the skin. When an irritant affects the investment of a viscus the pain is already cutaneous, but, as in the inpacking, the surfaces are distorted, the corresponding layer of outside skin has often been drawn away from the underpart of it which is still attached to the viscus affected.

I am, Sir, yours faithfully,

Cambridge, Feb 19th, 1921.

CLIFFORD ALLBUTT.

X RAY TREATMENT OF RINGWORM.

To the Editor of THE LANCET.

SIR,—I am of the opinion that the warning and recommendation of the Medical Defence Union (THE LANCET, Jan. 1st, p. 48) is an unnecessary one. In the first place, workers of X ray treatment for ringworm have already gone through the mill of prejudice and fear from parents who had heard of dire results, in days not long since passed, when the skeleton of "burnt heads" and "no hair" was put forward—with, undoubtedly, some reason—owing to unfortunate results obtained by early workers in producing permanent alopecias. Unfortunately, rumours of this kind are always exaggerated as they go from one parent to another. Some of the tales related by parents to me some six or seven years ago would have been sufficient, if really credited, to have produced hair-raising results without the application of X rays to both "operator" and "operated on."

At the present time I am happy to say that, after having treated over 800 cases without a single failure, it is now quite a different tale, and that parents may almost be said to be clamouring for X ray treatment rather than go on for months with drug treatment. True, there are some cases, but a very small number, who from idiosyncrasy develop a definite reaction and suffer from erythema, or even a slight pustular eruption, as the result of X ray application, but under appropriate remedies these quickly subside and the resulting growth of the hair is in no way retarded or diminished; in fact, I am of the opinion that as a result of the increased supply of blood during this period to the hair follicles, that the growth is often more rapid. Then why raise the voice of the general practitioner in warning parents against such trivial occurrences, or even raise the suspicion of the general practitioner himself, who, in most cases, is not cognisant of the pros and cons of the working of X ray treatment for ringworm?

800 cases means 4000 exposures, the carrying out of each exposure means a separate operation necessitating the maximum attention to detail. As Dr. W. Mitchell, of Bradford, says, the X ray treatment of tinea tonsurans is the most exact and exacting form of treatment there is. I would go further and say it is also most tedious and monotonous, varied only by the extra burden of a fractious child. I work also with a small milliampèrage (0·5 m.a.) with current 80 volts 5 amperes. In all cases the whole head is epilated by the Kienboch method with a light tungsten target tube, the five exposures being checked by Sabouraud and Noire's pastilles. After-treatment needs great care, and although Dr. C. W. Hutt considers it necessary in 1 out of 10, I make every child attend regularly for a fortnight to have the necessary stumps epilated by the school nurses to ensure that no form of infection is left. Some children are fit to return to school at the end of three weeks, the general average is, however, about 28 days.

In my opinion the essential points for success in the Kienboch method of treatment are to direct each irradiation at right angles to the direction of irradiation of adjacent areas and to aim not at a point in the centre of the vertex of the lower occiput or of the side of the scalp, but toward the outer margin of these areas, so that half the dose goes on to the scalp and half on to the shield protecting the face and the neck. If these precautions be taken there is no risk of over-exposure at the overlapping margins of the rayed areas. In practice the dosage works out so nicely that every part receives an equal amount and depilation is total and complete without anywhere a sign of over- or under-exposure.

The chief causes of failure are: (1) Under-exposure, so that an imperfect defluvium of the hair takes place and infected hairs are left; (2) omission of a focus of disease in the exposure; (3) insufficient thoroughness in the after-treatment. With recent methods of treatment and ordinary care there should be no failures.

I am, Sir, yours faithfully,
VICTOR J. BLAKE, M.B., B.S. Lond.

Portsmouth, Feb. 8th, 1921.

THE FINE CHEMICAL INDUSTRY.

To the Editor of THE LANCET.

SIR,—We, the undersigned, makers of fine chemicals, extended our research and manufacturing plant at the urgent appeal of the State during the tremendous years that followed 1914 in order to secure those essential products of science without which victory could not be attained. The full record of wartime achievements in the sphere of fine chemicals would read like a romance were the full history disclosed. This key industry is now endangered, and unemployment is rife in it, owing to the flood of imports from abroad which, among other circumstances, the present condition of the exchanges makes devastatingly possible.

We desire to submit to public knowledge the following facts:—

1. The application of chemical science to industry is a necessary factor for the preservation of our world position in commerce. It is also true to say not only that the chemist and the laboratory are in the first line of national defence, but are pivotal in the development of our industrial and commercial resources and wealth.

2. At very considerable cost essential plant was erected during the war years, and all of it can now be put to peaceful purposes for the continuance in this country of a fine chemical industry not inferior to Germany's. But under the present unfair economic circumstances this plant must become idle and useless unless the State takes measures for its safeguarding.

3. The *Fine Chemical Industry, mobilised and expanded* in the hour of the nation's needs, provided during the war—to give a few examples—(*a*) essential medicinal preparations for naval, military, and civilian hospitals; (*b*) the higher forms of explosives and gases; (*c*) photographic chemicals for aerial use; (*d*) research chemicals, without which the development of many new industrial processes would have *been impossible.*

4. British science is no whit inferior to that of competing nations, nor are British chemical manufactures inferior in quality.

We feel it is our bounden public duty to make known to the country the national importance of an industry which is indeed a key to the unlocking of many doors of economic wealth in the future.

Feb. 19th, 1921.

THE OPERATIVE TREATMENT OF PROLAPSE.

To the Editor of THE LANCET.

SIR,—In reply to Mr. J. P. Lockhart-Mummery's letter in your issue of Feb. 19th I did not advocate the use of "paraffin wax injections" in a general sense, but only the "submucous *injection of paraffin wax*," as described by me in THE LANCET, 1901, vol. ii., p. 759. This may sound egotistical, but it is the attention to detail that makes all the difference. Consideration for your space will not permit me to reproduce the technique here, but the most essential points are that the paraffin is injected into the submucous layer only at a temperature just above its melting point, so that it solidifies at once and does not travel, while the prolapse is still outside the anus, and so as to constitute separate nodules arranged circumferentially around the rectum in definite tiers. With these precautions I fail to see how a "tunnel stricture" could result; probably in the case he mentions the wax had been introduced in too fluid a state and had completely surrounded the rectum in a continuous sheet. At any rate, I have never seen any sign of stricture in any of the 29 cases I have treated by this method, and the only trouble of any kind has been slight suppuration of the wound of the plastic portion of the procedure in two of the cases; in one of these some particles of wax were discharged from the lowest tier, but without detriment to the ultimate result. From letters received from time to time from surgeons who have followed the details of my technique I know that others, besides myself, can obtain good results. Within the last month I have received two such letters, from Mr. A. H. Godson, F.R.C.S. Eng., of Oldham, and Dr. G. A. Robinson, of Nottingham, each reporting a recent success. I do not know the details of their cases, but Dr. Robinson describes the success in his patient as amazing."

However, I have never considered nor advocated my method as an ideal procedure; I merely state that results can be obtained with it at least as successful, both immediately and remotely, as those by any other published method, and that with a very much simpler and shorter after-treatment. Like Mr. Lockhart-Mummery, I would much prefer to dispense with the introduction of any foreign body into the tissues, and have therefore tried other methods, including that of Moschowitz, as I mentioned in my previous letter—a method which appeals to me strongly as being far more scientifically designed than either Mr. Lockhart-Mummery's method or my own—but with inferior results. I have not tried Mr. Lockhart-Mummery's method, as one feels rather shouldered off from an operation of which the author says, "sepsis later is almost certain to occur ...... and is, in fact, desirable." I can imagine that the aid of sepsis, once invoked, might prove at least as difficult to control and as fraught with ultimate dangers as that of paraffin wax. I am the more disposed to give it a trial, however, since it would appear, from Mr. Aslett Baldwin's remarks in the discussion following the reading of Mr. Lockhart-Mummery's paper, that by the use of gauze soaked in 1 in 1000 proflavine solution this can be prevented and the after-treatment simplified.

From Mr. Lockhart-Mummery's silence on the point I presume he now admits that his analogy of his operation to the radical cure of hernia was not conceived in his happiest vein.—I am, Sir, yours faithfully,

Manchester, Feb. 20th, 1921. ARTHUR H. BURGESS.

AS OTHERS SEE US.

To the Editor of THE LANCET.

SIR,—Since medical practice came within the sphere of politics, no one who mixes much with ordinary people can doubt that the status of the general practitioner has steadily declined. And the interesting question arises: Is this an early symptom, indicating the onset of a disease, whose more serious manifestations may be prevented by a little timely attention to moral hygiene; or is it a physical sign, indicating that appreciable structural changes have already taken place, for which the best that can be done is but of the nature of a palliative, or of a valetudinarian regimen calculated to preserve a long period of invalidism before the final collapse? Another interesting question is *this*: Has the disease, whatever it is, but lately appeared; or is it merely that new instruments of precision have made its diagnosis easier and more obvious?

First of all, then, what has happened to our status since 1913? We have always had hostile critics who mistrusted our alleged skill and knowledge, as well as our assumption of philanthropy. But these critics were numerically few. The generality of people took us pretty much at our own more complacent valuation, and attributed to us not only knowledge which we all know to be a grotesquely excessive estimate, but a public and self-sacrificing spirit beyond that attributed to any other class of men. Now, it is an undoubted fact, at last recognised even by our educationalists, that a man, woman, or child tends to live up or down to his reputation. Give a dog a bad name and he will soon deserve it. Admiration often breeds many of those qualities which evoke admiration. Gratitude breeds generosity. Praise often breeds nobility. And I think it can fairly be said that, although the average doctor was, as he is to-day, just an average man, and although, naturally, among so many thousands of average men were to be found the usual proportion of the sordid, the unimaginative, the inherently vulgar, the men whose only notion of successful living was that of the constitutional "wrong 'uns" of society, based on the rule, "Get all you can; give as little as you can"—what we may call the Cad's Code; yet, among the rest, most men took a personal pride in justifying, to a greater or less extent, the popular estimation of the doctor's moral code. Of course, one need not be much of a cynic to realise that many manifestations of apparent public spirit and generosity were not entirely of æsthetic or altruistic origin. But there certainly was a very large element of genuine honour, genuine professional pride, of desire to "play the game." The tradition of the Hippocratic oath still had some potency.

I am not in a position to state what is the present general view of the doctor's standard of conduct among the middle classes, but among the wage-earning classes opinion has entirely changed. To an increasing extent the doctor is regarded as a tradesman in the worst sense. Unless there is overwhelming individual evidence to the contrary, it is apt to be taken for granted that the general practitioner—which term is now almost synonymous with panel practitioner—is the sort of man I have described above as the decadent exception, the man whom we can justly characterise as the Cad in Medicine. Is the working man right in his estimate? If not, to what is his change of opinion due? Unless we analyse the symptom, trace its causation and deal with it, it is pretty certain that, whether or not it is true at this moment, it will, by the mere force of suggestion, shortly become true.

I have taken a good deal of trouble to find out what are the facts on which the working-class view of the doctor and the doctor's code is based; and I have been driven to the conclusion that his judgment has some basis in real and actual facts—facts indicating morbid change. I believe that, to some extent, an actual change has occurred in the doctor's morale and its manifestations. In spite of its many good points and beneficent potentialities, the Insurance Act has not, on the whole, altered for the good the attitude of the average practitioner towards his work and towards his patients. On the contrary, it has tended to materialise it. I do not believe that this was inevitable or inherent in the scheme itself, but actually, owing to concomitant circumstances, it has so worked out.

But this real change has not, so far, been sufficiently great or general to account, by itself, for the much greater change in public opinion. There has, beyond doubt, been an increasing number of men, who, having discovered that under the panel system it was possible to get a substantial income in return for a minimum of indifferent service, have taken advantage of that discovery to play the parasite on their fellow men. But the majority of practitioners have still been mainly influenced by the traditional code, combined with such modicum of the artistic spirit, the impulse to efficient self-expression, as they happened to embody. In other words, whilst keen on getting as much money as they could, they have been little less keen on doing their work as well as they could. Such men, I believe, make up the bulk of our profession; as I believe, in spiritual essence, they make up the bulk of our countrymen.

What, then, is the additional factor responsible for the increasing loss of good repute which we have suffered? It is needful only to have attended almost any of the meetings (other than purely scientific ones) called by members of our profession within the last few years, or to have read the letters and articles on what we may call medical politics contributed to various organs of medical opinion—especially those uninfluenced by old traditions—to understand and to realise how the change has been brought about. The incessant talk about money, and the almost complete absence of any expression implying a realisation of the responsibilities and sacredness of our craft or of our duties in utilising for the public welfare the special knowledge with which we have been entrusted, have done their work. In other words, we have again been taken at our own valuation. We are increasingly regarded by the wage-earning classes much in the same way as, justly or unjustly, the more prejudiced sections of the middle-class regarded the miners during their recent strike. So far as our public expressions have gone, we have taken up the line, which, quite excusably, however mistakenly, has been adopted by those who, with considerable justice, regard themselves as the economic victims of our industrial system. And we cannot plead their excuse. We may have our grievances against society, but they *are trivial. It is only needful to devote five minutes'* study to the national income and to the average available dividend, and to compare them with the average doctor's income, to realise that, so far from being economic victims, we are among the luckier grades of the privileged.

Such grievances as we have, let us try to get remedied by all means. But for Heaven's sake let us utilise our pseudo-scientific education in cultivating some sense of proportion. Our chief professional ethic should be directed to the maintenance of the purity of our professional code, and to the devising of the most effective social mechanisms to assist us in functioning *adequately. Of course, if our material existence is in* danger, and consequently abnormally intrudes on our attention, we cannot function properly. And many workers are in such a position. They, excusably, talk about little else than getting their wages raised. It is the merest humbug to pretend that we are in any such position.

It is high time that the great silent mass of the profession asserted itself, and took steps to demonstrate to the public that a doctor is something more than a grouser; that we are not just profiteers, prepared to use our monopolist position in order to hold the community to ransom; that it is from honest motives that *we feel a man's pulse with our right hand, not merely* to hold his attention while we pick his pocket with our left. It is high time also that the ethical committees of the profession woke up and realised what is at stake. It should not be such bodies as lay insurance committees that the slackers and parasites of our profession should fear, but the condemnation and practical ostracism of all that is decent, scientific, artistic, honest, and public-spirited within our own ranks. And I am firmly con*vinced that these characteristics still mark* the great majority of English practitioners, unobtrusive and unvocal though they are.

I am, Sir, yours faithfully,

Harford-street, Stepney, Feb. 19th, 1921. HARRY ROBERTS.

THE SEPARATION OF PRESCRIBING AND DISPENSING.

To the Editor of THE LANCET.

SIR,—The communication by Mr. H. C. Richards under this heading, which appeared *in THE LANCET* of Feb. 5th, invites comment. Mr. Richards states that "the pharmacist is primarily licensed to keep open shop for the retailing and dispensing of poisons *only*, whereas the apothecary's assistant is a qualified dispenser of all substances used in medicine—*poisons or otherwise*" (the italics are mine). From which the inference might be drawn that the apothecary's assistant is legally qualified to dispense, but the pharmacist, legally, should *limit his dispensing* to poisonous substances.

As a matter both of fact and (unfortunately) of law, anyone may *dispense* any drugs, but must not *sell* any poisons which are at present included in the schedules *of the* Pharmacy Act, or may be in future added to those schedules, on the instance of the Council of the Pharmaceutical Society and approved by the Privy Council. The apothecary's assistant, as far as the dispensing of drugs *is concerned, is precisely* on the same footing as the herbalist or the grocer. The Society of Apothecaries has authority to give a certificate to persons to act as dispensers to apothecaries only. As regards other dispensing, it has no powers not possessed by any trades-union.

The Pharmaceutical Society enjoys statutory authority to issue certificates of qualification for the practice of pharmacy in open shops. Its standard of efficiency is high, and is recognised as such in dispensaries, infirmaries, and hospitals throughout the country.

I am, Sir, yours faithfully,

J. O. BRAITHWAITE,

Editor of the "Year-book of Pharmacy."

Chingford, Feb. 15th, 1921.

*** We have received other letters in the same sense.—ED. L.

DURATION OF THE VENTRICULAR COMPLEX.

To the Editor of THE LANCET.

SIR,—In your issue of Sept. 4th, 1920, Dr. H. Wallace Jones, of Liverpool, published a very interesting note on a case in which an electrocardiograph was taken 12 hours after spontaneous respiration had ceased. The author states that the tracing shows normal rhythm, with some lengthening of the ventricular complex. I should like to point out that the lengthening of the complex is very considerable, and that this is a very uncommon and a very interesting phenomenon. In Dr. Jones's tracing the rhythm of the pulse is 52, and the duration of the ventricular complex about 0·55 sec. Normally, the duration of the complex with this *rhythm of pulse would be 0·40* sec., with a standard deviation of 0·015 sec.[1] In pathological cases lengthening is sometimes seen, but I do not think that such a considerable prolongation as in Dr. Jones's case has been seen before.

I am, Sir, yours faithfully,

L. S. FRIDERICIA, M.D.,

Professor of Hygiene at the University of Copenhagen.

Feb. 18th, 1921.

THE TREATMENT OF DIPHTHERIA CARRIERS.

To the Editor of THE LANCET.

SIR,—I regret the delay in replying to Dr. J. L. Brownlie's letter published in your issue of Dec. 11th, 1920, and referring to an article (THE LANCET, 1920, ii., 994) by Dr. A. R. Fraser and myself on the treatment of diphtheria carriers. As Dr. Fraser is in South Africa and I wished to have his views first, this delay was unavoidable.

We feel we have excellent reasons for preserving the distinction between "carriers" and "positive throats." The definition we gave of a "carrier" is a general one; examined critically it includes our "positive throats." Later we drew our rough line of distinction. In doing so we had no intention of taking a liberty. The term "carrier" and its meaning are now well known to many of the laity, and a "carrier" is regarded by not a few as one who ought to be kept segregated, like a leper. They may be right in some cases; they would be wrong in others, and in such cases great hardship results to the individual labelled a "carrier." We have personal knowledge of such sad cases. Further, not all the throats diagnosed in practice and in hospitals as positive are proved to have present virulent Klebs-Löffler bacilli. For these and other reasons we feel strongly that we must have absolute proof of the long persistence of virulent organisms before we apply the term "carrier" to an individual. For the many others who have presumably infective throats we had to find another term, and we choose to call such "positive throats."

We trust we have satisfied Dr. Brownlie as to our views and intentions without further discussing the matter in his letter. Our general aim is the same—to show, if possible, that the outlook for the "carrier" (even in the worst sense of the term) is by no means hopeless, as many appear to believe, especially American writers.

I am, Sir, yours faithfully,

A. G. B. DUNCAN,

Assistant M.O.H., Hull.

Feb. 21st, 1921.

QUININE TREATMENT OF MALARIA.

To the Editor of THE LANCET.

SIR,—Will you allow me to rectify an omission in my paper on the Treatment of Malaria by Quinine, which appeared in your issue of Feb. 12th? The last sentence—"This aspect of the question ......"—was borrowed without acknowledgment from a paper by Lieutenant-Colonel J. W. Cornwall, I.M.S., read before the Indian Science Congress of 1919, and is contained in the proceedings of that Congress published in a special number of the *Indian Journal of Medical Research*, p. 88. I much regret the omission.

I am, Sir, yours faithfully,
P. HEHIR.

Westward Ho! Feb. 16th, 1921.

Medical News.

UNIVERSITY OF CAMBRIDGE: DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—The Special Board for Medicine, on the recommendation of the Committee on Medical Radiology and Electrology, has approved the grant of the Diploma in Medical Radiology and Electrology to Drs. J. E. A. Lynham, A. E. H. Pinch, W. J. Turrell, A. E. Barclay, and F. Hernaman-Johnson.

UNIVERSITY OF BRISTOL.—At examinations held recently the following candidates were successful:—

EXAMINATION FOR DEGREE OF M.D.

Adolph Reeve Heber.

FINAL EXAMINATION FOR DEGREES OF M.B., CH.B.

Part II. (completing examination).—William Harris Royal and Majorie Wadsworth (first-class honours).

Part I. only (including Forensic Medicine and Toxicology).—William Austin Jackman and Percy Phillips.

Part I. only.—Phyllis Beames, Macdonald Critchley, John Rukin Duerden, Winifred Grace Nott, John Augustin Prichard, William Kenneth Armstrong Richards, and Victoria Sophia Tryon

FINAL EXAMINATION FOR DIPLOMA IN DENTAL SURGERY.

Norman Henry Bodenham.

EXAMINATION FOR DIPLOMA IN PUBLIC HEALTH.

Part II. (completing examination).—Frederick Vaudrey Cant, Allan Dumbreck Fraser, and Geoffrey Commeline Williams.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—The Morison lectures will be delivered by Sir Frederick Mott, F.R.S., in the Hall of the College, 9, Queen-street, Edinburgh, at 5 P.M., on March 7th, 9th, and 11. The subject will be the Psychopathology of Puberty and Adolescence, and each lecture will be illustrated by drawings and lantern slide demonstrations.

LONDON HOSPITAL MEDICAL COLLEGE (*University of London*).—A course of 12 lecture-demonstrations on Gonorrhœa will be given by Mr. E. R. Townley Clarkson and Dr. A. Malcolm Simpson (chief assistant to the genito-urinary department of the hospital), on Tuesdays and Thursdays (men), and Wednesdays and Fridays (women), at 4.30 P.M. The course is intended for senior students of the hospital and for medical practitioners, who are invited to attend.

MEDICAL SOCIETY OF LONDON.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W., on Monday, Feb. 28th, at 8.30 P.M. A discussion on the Chemical Estimation of Gastric Function will be introduced by Dr. J. H. Ryffel and Dr. J. A. Ryle. Dr. T. I. Bennett, Dr. R. L. M. Wallis, Mr. E. C. Dodds, Dr. G. Graham, Dr. C. Bolton, Dr. R. Hutchinson, and Dr. W. H. Willcox will be among the speakers.

ROYAL INSTITUTION.—On Saturday next, March 5th, at 3 o'clock, Sir Ernest Rutherford will deliver the first of a course of three lectures at the Royal Institution on Electricity and Matter, and on Thursday, March 10th, Dr. G. C. Simpson, director of the Meteorological Office, commences a course of two lectures on the Meteorology of the Antarctic. The Friday evening discourse on March 11th will be delivered by Dr. J. Freeman on Medical Idiosyncrasies.

INDUSTRIAL WELFARE CONFERENCE.—The Industrial Welfare Society is arranging a conference to be held at the Mansion House on March 2nd. The Lord Mayor will preside, and the speakers will include the Duke of York, the Right Hon. E. Short, M.P., the Right Hon. H. A. L. Fisher, M.P., the Right Hon. J. R. Clynes, M.P., Alderman Sir Charles C. Wakefield, and Sir William H. Ellis, D.Sc.

DR. O. K. Williamson, who was recently appointed to the Chair of Medicine at University College, Johannesburg, does not take up his new duties until February, 1922, and will not be leaving England before the end of the present year.

TUBERCULOSIS SOCIETY OF GREAT BRITAIN AND IRELAND.—A meeting of this society will be held at the Margaret-street Hospital, London, W., on Monday, Feb. 28th, at 7.30 P.M., when Dr. W. Gordon will read a paper on Rain-bearing Winds and Tuberculosis.

THE RE-EDUCATION OF THE DISABLED.—A lecture on this subject will be given by Captain J. Manclark Hollis, secretary to the Village Centres Council, on Wednesday, March 2nd, at 8 P.M., at the house of the Royal Society of Arts, John-street, Adelphi, London, W.C.

THE Royal Faculty of Physicians and Surgeons, Glasgow, has recently sustained a loss in the death of its secretary and librarian, Mr. Alexander Duncan, B.A., LL.D., who died on Feb. 14th. Mr. Duncan, who had held his appointment for over 55 years, had an all-round knowledge of medical literature. He devoted much time to the preparation of a catalogue of the extensive medical library under his supervision and was the author of a serviceable history of the medical profession in the West of Scotland.

ROYAL STATISTICAL SOCIETY.—The council will, in November, 1921, award the Frances Wood Memorial Prize, value £30, *for the best investigation of any problem* dealing with the economic or social conditions of the wage-earning classes. The subject is to be chosen by the competitor and is to be treated on statistical lines. Essays must be sent, not later than July 1st next, to the Honorary Secretaries of the Royal Statistical Society, 9, Adelphi-terrace, London, W.C. 2, from whom further information may be obtained.

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES. The second of a course of five lectures on Analytical Psychology will be given by Dr. Maurice Nicoll on Monday, Feb. 28th, at 5.15 P.M. A course of ten lectures on Elementary Psychotherapy will be given by Dr. H. Crichton Miller on Fridays, at 5.15 P.M., beginning May 6th. The fees for each course are: medical practitioners, £2 2*s.*, medical students, £1 1*s.*, and tickets should be taken in advance from the honorary lecture secretary at the clinic, 51, Tavistock-square, London, W.C. 1.

THE Institut Français du Royaume Uni will be opened at 1–7, Cromwell-gardens, S.W., on Saturday next, Feb. 26th, at 3 o'clock, under the presidency of the French Ambassador, the Comte de Saint Aulaire. The French Minister of Education, M. Léon Bérard, will represent his Government, and the English Board of Education and the London County Council will also be represented. Three delegates are expected from the Paris Municipal Council and from the University of Paris. Among the latter will be Mons. Appel, the Rector of the University, and Mons. Henri Bergson. The Rector of the University of Lille is also expected to be present, that University being the parent of the movement.

FEDERATION OF MEDICAL AND ALLIED SOCIETIES. A meeting of the Executive Council was held on Feb. 15th at 11, Chandos-street, London, W. Two letters from the Minister of Health were read stating his gratification at the work already accomplished by the Federation, and reaffirming his view that such a body should represent, not its own interests primarily, but the wider interests of the nation. The council then considered the new regulations drafted by the Secretary of State under Section 7 of the Dangerous Drugs Act, 1920. The Pharmaceutical Society of Great Britain pointed out that certain clauses of the Bill affecting its members were unworkable and that the time allowed for their consideration and the representation of views had been inadequate. Pending the receipt of the views of the constituent bodies in the Federation a letter had been sent by the council to the Under Secretary of State on Feb. 9th asking for an extension of the period provided for the representation of the views of interested bodies. The Under Secretary replied that he would gladly receive representations from the Federation, and hoped they would be made at an early date. A letter was also received on this matter from Captain W. E. Elliot, M.P., secretary of the Medical Committee of the House of Commons. The interests of the insured person in connexion with the new medical record cards were further considered. Dr. H. J. Cardale, representing the Association of Panel Committees in the Federation, showed the cards and fully explained the method of using them. The meeting was of opinion that the principle of keeping such records could not be condemned, and that six months' trial of the actual cards issued would demonstrate their value or their faults.

ON the recommendation of the Minister of Health, the King has appointed Mrs. Ellen Frances Pinsent to be a Commissioner of the Board of Control to fill the vacancy caused by the retirement of Miss Mary Dendy.

League of Red Cross Societies.—The third annual meeting of the board of governors will be held in Geneva on March 28th. The members of the board for this year are as follows: Mr. Henry P. Davison, American Red Cross, chairman; Hon. Sir Arthur Stanley, British Red Cross; Mons. de la Boulinière, French Red Cross; Count Giuseppe Frascara, Senator, Italian Red Cross; Professor Arata Ninagawa, Japanese Red Cross; Count de Pena Ramiro, Spanish Red Cross; Dr. F. Block, Swedish Red Cross; Dr. M. Calmon du Pin e Almeida, Brazilian Red Cross; Colonel C. Bohny, Swiss Red Cross; Dr. E. Andreae, Argentine Red Cross; Dr. A. Depage, Senator, Belgian Red Cross; the Viscountess Novar, Australian Red Cross; Dr. F. Svendsen, Danish Red Cross; Dr. Yevrem Jouyovitch, Serbian Red Cross; Sir David Henderson, director-general, vice-chairman; Professor William E. Rappard, secretary-general. The General Medical Department of the League will be in charge of Professor C. E. A. Winslow, who has five months' leave of absence from Yale University. He is now in Geneva.

Royal Free Hospital: Professorial Unit.—Professor A. Louise McIlroy, whose appointment to direct the new obstetrical and gynæcological unit at the Royal Free Hospital, London, was announced in our last issue, was educated at the Universities of Glasgow, London, Berlin, Vienna, and Paris, and holds the diploma in midwifery of the Rotunda Hospital, Dublin. She has occupied appointments as assistant surgeon at the Glasgow Female Lock Hospital, district obstetric physician in charge of the West End Branch of the Glasgow Royal Maternity Hospital, assistant gynæcological surgeon at the Royal Samaritan Hospital, Glasgow, and senior assistant to the Muirhead Professor of Obstetrics and Gynæcology at the University of Glasgow. From 1915 to 1919 she was surgeon-in-charge of the Girton and Newnham unit of the Scottish Women's Hospitals for Foreign Service, which was stationed at Salonika and Belgrade. Since 1919 she has been gynæcological specialist in the 82nd General Hospital at Constantinople, in which she acted as surgical specialist during the absence of the senior surgeon. The unit of which Professor McIlroy will have charge contains 68 beds, of which 35 are in the Royal Free Hospital in Gray's Inn-road and 33 in the Marlborough Maternity Block, Endsleigh-street. All the wards are small, containing from two to ten beds. It is intended to receive not only patients who pay nothing for maintenance and treatment, but also patients who can pay up to £4 a week to cover the cost of maintenance. The professor will be assisted by first and second assistants, both of whom will be giving full time to the work of the unit. In addition there will be the registrar of the unit and three house physicians.

Aberdeen Royal Infirmary and Lunatic Asylum. The annual meeting of the corporation of the Royal Infirmary and Lunatic Asylum was held at the infirmary on Feb. 9th, Lord Provost Meff presiding. The chairman pointed out that annual donations had increased by £6200, but that costs were still exceptionally high. If the general public wished to keep the infirmary off the rates they must subscribe generously towards its maintenance. Mr. George Davidson, chairman of the infirmary board, submitted the infirmary annual report and moved its adoption. It was recorded that 55 per cent. of the in-patients came from the city and 45 per cent. from the county. He chronicled the equipment of a new pathological laboratory and the development of the scheme for the treatment of venereal disease, also the completion of the nurses' home at Albyn-terrace and the installation of electric light and central heating at the Cults Convalescent Hospital. An important discussion then took place on the question of demanding payment from patients treated at the infirmary in order to place the institution on a sound financial basis. A motion to submit to the directorate for their consideration the question of reserving a portion of the hospital for paying patients, or of requiring payment from all above a certain income, was withdrawn after some discussion. Mr. Andrew Davidson, chairman of the asylum board, submitted the annual report of the asylum. He explained that the deficit of £8000 on the year's working was caused by the fact that they had to fix their charges on the parish council and on private individuals a long time in advance, and the increases in cost had been out of all proportion to that anticipated. The directors had considered the question of establishing some sort of a clinic, apart from the asylum, where patients could be treated in the early stages of mental trouble. They were advised, however, that the fact of such a clinic being managed by the directors of the asylum would diminish its chances of success. It seemed to him, however, that there was an opening for some independent person to start a clinic of this kind.

Inter-Departmental Committee on Patents.—This Committee has been established by the Privy Council, with the following terms of reference:—

(1) To consider the methods of dealing with inventions made by workers aided or maintained from public funds, whether such workers be engaged (*a*) as research workers, or (*b*) in some other technical capacity, so as to give a fair reward to the inventor and thus encourage further effort, to secure the utilisation in industry of suitable inventions, and to protect the national interest; and

(2) to outline a course of procedure in respect of inventions arising out of State aided or supported work, which shall further these aims and be suitable for adoption by all Government Departments concerned.

As at present constituted, the Committee consists of the following members:—

Mr. Kenneth Lee, LL.D. (Chairman); Mr. W. St. D. Jenkins, C.B.E., Admiralty Director of Contracts; Mr. F. E. Smith, O.B.E., F.R.S., Admiralty, Director of Scientific Research; Air Vice-Marshal Sir E. L. Ellington, K.C.B., C.M.G., C.B.E., Air Ministry. Director-General of Supply and Research; Mr. H. W. W. McAnally, C.B., Air Ministry, Assistant Secretary; Mr. P. W. L. Ashley, C.B., Board of Trade, Assistant Secretary, Industries and Manufactures Department; Colonel W. H. D. Clark, O.B.E., Board of Trade, Assistant Comptroller of the Patent Office; Sir H. Frank Heath K.C.B., Department of Scientific and Industrial Research, Secretary; Mr. A. J. Stubbs, M.Inst.C.E., M.I.E.E., General Post Office, Assistant Engineer-in-Chief; Mr. H. H. Dale, C.B.E., M.D., F.R.S., Medical Research Council, Head of Department of Biochemistry and Pharmacology; Mr. W. J. Coombes, Ministry of Munitions; Lieutenant-Colonel P. K. Lewes, C.M.G., D.S.O., R.A., War Office, Assistant Director of Artillery; Mr. P. Tindal Robertson, Barrister-at-Law, Royal Commission on Awards to Inventors, Secretary; Sir R. A. Gregory, F.R.A.S., Editor of *Nature;* Mr. D. M. Kerly, K.C.; Sir Charles A. Parsons, K.C.B., LL.D., D.Sc., F.R.S.

The Secretary to the Committee is Mr. A. Abbott, to whom all communications should be addressed at 16 and 18, Old Queen-street, Westminster, London, S.W.1.

Union of Medical Practitioners: Leicester Subdivision.—At the annual meeting held on Feb. 10th the following officers were elected for the ensuing year: Chairman, Dr. A. M. Crosfield; vice-chairman, Dr. G. H. Crofts; treasurer, Dr. Astley V. Clarke; honorary secretary, Dr. W. Moffat Holmes. The annual report states that the scheme of collective locum tenencies for the summer holidays, inaugurated during 1919, was successfully continued during last summer. Twenty doctors availed themselves of the facilities afforded by the scheme, and contributed £275 5*s.* to the pool. The expenses amounted to £4 2*s.* 8*d.*, being cost of books, posters, stationery, &c., leaving £271 2*s.* 4*d.* for distribution amongst the practitioners who attended patients under the scheme. The scheme for collective locum tenencies during sickness or short absences initiated in the early part of last year had been continued, and was now in operation. It had proved very useful in several cases. At the annual meeting of this subdivision held in February last year it was resolved "that use should be made of the Public Medical Service Rooms, East Bond-street, for the purpose of a club for the medical men of Leicester and Leicestershire." Effect was given to this resolution, and alterations were made and billiard, reading, and writing rooms provided. The committee had had under consideration the matter of school certificates, and had reaffirmed the resolution that school certificates for children attending elementary schools should not be provided by medical practitioners, except where paid for by the education authority. Representations had been made to the Ministry of Health Committee of the B.M.A. claiming that where the Ministry undertakes the partial support of existing hospitals or establishes fresh ones, men who have taken the trouble to obtain the higher degrees or diplomas, or who who have had considerable special experience during the war, should have an opportunity of being appointed to the staffs of these hospitals.

Leicester Public Medical Service.—A meeting was held on Feb. 10th, when the report of the board of management was read. The report recorded the numbers of subscribers to the various sections of the service: in the first half of 1920 these amounted in all to 39,883, and in the second half to 39,139. In addition over 12,0 0 State insured members of the friendly societies were paid for through the service. The rate per capita paid to "acting members" of the Service showed a substantial advance. The board had continued the arrangement whereby free medical treatment was provided for the uninsured blind of Leicester, under the care of the Institution for the Welfare of the Blind, the members of the Cripples' Guild, and the Wycliffe Society for helping the Blind. The Education Committee had continued the arrangement with the board for the school clinic work to be carried on at the Central Dispensary, and the following number of new cases, in addition to many others, received treatment during the year: vision, 778; nose, ear and throat, 843; teeth, 3529. The board had again entered into an arrangement with the Leicester Guardians for the dispensing of the necessary medicines for the outdoor sick poor. Arrangements had been made with the Ministry of Health for the use of a consulting-room at the Central Dispensary, for the examination by the regional medical officer of certain patients insured under the National Insurance Act. A proposal that it might be advantageous to members of the service if arrangements were made for them to obtain drugs, &c., through the Public Medical Service had been carefully considered by the Finance and General Purposes Committee, who recommended that the proposal be adopted. Several members had availed themselves of the arrangement, the accounts up to the end of the year amounting to £46 11*s.* 4*d.* In connexion with the agreement between the Public Medical Service and the Foresters and Oddfellows Medical Associations the board directed the special attention of "acting members" to the following clause respecting voluntary subscribers, with particular reference to the exception in cases of emergency:—

> "They do not bind themselves to make visits between 8 P.M. and 9 A.M. in response to calls received within these hours, nor to make special visits in the day-time unless notice has been given before half-past nine o'clock in the morning. For visits made at the member's request under any of the conditions specified a charge of 3*s.* 6*d.* will be made, *except in cases of emergency.*"

CENTRAL COUNCIL FOR DISTRICT NURSING IN LONDON.—The annual meeting of the council will be held at the offices of the Metropolitan Asylums Board, Embankment, London, E.C., at 2.30 P.M., on Monday, Feb. 28th, when the provision of home nursing for persons of limited means will come up for consideration.

LONDON SCHOOL OF TROPICAL MEDICINE: RESEARCH EXPEDITION TO BRITISH GUIANA.—Some time ago the Colonial Office was requested by the Government of British Guiana to investigate the subject of filariasis, a disease affecting at least 50 per cent. of the population of that country. The matter was referred to the London School of Tropical Medicine, which unfortunately could not at that time spare funds for the purpose, in view of the claims of expedition to the Pacific Islands to test the salvarsan compounds in their action on filarial disease. The Pacific Expedition having returned, and a second request having been received from the Colonial Office to look into the importance of endemic filariasis in British Guiana, alleged by Dr. F. G. Rose to be very urgent, an expedition was organised and financed by the School under the able leadership of Professor R. T. Leiper, who will be supported by a strong body of assistants, with Dr. G. M. Vevers as chief of the helminthological department and Dr. John Anderson to conduct researches upon the therapeutic and pathological aspects of the disease. The whole subject of filariasis will be investigated on the spot, especially with a view to devising measures for prevention and effective treatment of the developed disease. The lines to be followed will be those already found so successful in bilharziasis, different metals being tested as to their therapeutic value in filariasis. The expedition, we learn, starts this week.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee held on Feb. 8th 17 cases were considered and £245 voted to 15. The following is a summary of some of the cases relieved:—

M.R.C.S.E., aged 80. Married, practised in London. Suffers from facial neuritis following paralysis. Dependent on daughter, who supplements her income by taking paying guests. Applicant receives the old-age pension. Voted £13.—M.B., C.M. Edin., aged 67, married. Was a temporary assistant medical officer at a mental hospital. Asks for help to meet expenses. Step-daughter, aged 45, dependent owing to being deaf since birth. A married daughter, a war widow, gives help occasionally. Wife takes boarders to supplement income. Has had to sell furniture to make ends meet, and within the last 12 months has paid off £100 for debts. Rent and rates, £69 per annum, amount owing £36. Voted £26 in 12 instalments.—Daughter, aged 48, of M.R.C.S. Eng. who was a surgeon-major in India and died in 1881. Applicant suffers from bad health owing to munition work during the war. She lives with her sister, and they both receive a pension from the India Office of £56 and a present from friends of £12. Their furnished cottage costs 12*s.* 6*d.* per week. Voted £10 in two instalments and a special grant of £10.—Widow, aged 36, of M.R.C.S. Eng. who practised at Rocking and died in 1919. Applicant having two delicate young children, took a house as a nursing home for child patients, but receipts do not cover expenses, and she has had to draw on her capital, the money realised by sale of late husband's practice. Her husband had five older children by his first marriage. Owns house, but it is mortgaged. Voted £20.—Daughter, aged 70, of M.R.C.S. who practised in Wiltshire and died in 1878. Applicant used to receive £100 per annum from friends, but this sum is no longer available, and her niece who looked after her has now to help her own aged mother. Old-age pension is being applied for. Voted £26 in four instalments.—Widow, aged 44, of M.B., C.M. Glasg. who practised at Hartley and died in 1909. Applicant left with three children. She acts as a companion-help at £60 per annum. Her eldest son is self-supporting, but she has to pay part of board for second boy, aged 17, who is apprenticed to the engineering; wages 19*s.* per week. Asks for help to meet expenses. Voted £20 in four instalments.—Daughter, aged 47, of M.R.C.S. Eng. who practised at Lincoln and died in 1908. Owing to ill-health she is entirely dependent on her mother, who receives a pension from the Fund. Relieved once, January, 1920, £12 in 12 instalments. Voted £12 in 12 instalments.—Widow, aged 54, of L.S.A. Lond. who practised at Cambridge Heath and died in 1911. Applicant has a cottage in Cornwall and earns money by taking boarders and tea-gardens, but owing to bad weather has been unable to meet expenses. Applicant has to find £2 per week for eldest son, who holds a scholarship of £30 at a mining school, and her younger son is an apprentice at 3*s.* 6*d.* per week. Rent and rates £12 per annum, and assurance for self and two sons £18 per annum. Relieved four times, £35; last time January, 1919, £10. Voted £10.

Subscriptions may be sent to the honorary treasurer, Sir Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

PSYCHOLOGICAL MEDICINE.—The third course of lectures and practical instruction for a diploma of psychological medicine will begin at the Maudsley Hospital on April 5th, when Sir Frederick Mott, F.R.S., will give the first of eight lectures on the Anatomy of the Nervous System. These lectures will be held on Tuesdays, at 2.30 P.M. Dr. F. Golla will give eight lectures on the Physiology of the Nervous System on Fridays, at 2.30 P.M., commencing on April 8th; and on Thursdays, at 2.30 P.M., Dr. Henry Devine will give eight lectures on Psychology, beginning on April 7th. Practical instruction and demonstrations will be given in connexion with these three courses of lectures. The second part of the course for the diploma will be held in October and details will be announced later. The fee for the whole course is £15 15*s.*, for either part separately £10 10*s.* The fee for a single series of lectures in Part I. is £4 4*s.* Inquiries should be addressed to the Director of the Pathological Laboratory, Maudsley Hospital, Denmark Hill, London, S.E.

Communications, Letters, &c., to the Editor have been received from—

NOTES ON CURRENT TOPICS.

Medical Record Cards.

A MEETING of the Medical Committee of the House of Commons was held on Monday, Feb. 21st, at Westminster, to consider the question of the new medical record cards issued by the Ministry of Health to panel practitioners. Lieutenant-Colonel **NATHAN RAW** presided. The meeting passed two resolutions, one to the effect that the principle of keeping a record was likely to result in permanent advantage to the insured person; and the second stating that the most jealous regard should be maintained for professional secrecy, which ought not to be infringed. It was decided that a question should be addressed to Dr. **ADDISON**, the Minister of Health, on the point whether the records could be called for in a court of law.

HOUSE OF LORDS.

THURSDAY, FEB. 17TH.

Chinese Flour and Dermatitis.

REPLYING to Lord **HARRIS**, the Earl of **CRAWFORD** (Chancellor of the Duchy of Lancaster) said that it had been very widely alleged that the Chinese flour which the Government had purchased was poisonous. It was suggested that it produced dermatitis, and it was even suggested that it was the cause of sleeping sickness—a complaint which originated, he believed, in about the only portion of this hemisphere to which Chinese breadstuffs had never penetrated. They might as well say that Chinese flour was answerable for housemaid's knee or any other conceivable ailment. The total quantity of Chinese flour that they had bought was less than 2 per cent. of our consumption. This flour was being consumed all over Europe. Analyses of it had been made for the Flour Mills Control Committee by public analysts by authoritative persons, and in every case the certificate of origin guaranteeing that the flour was made of pure wheat had been confirmed. The Ministry of Health, seeing these reports about sleeping sickness and dermatitis and so on, naturally interested themselves in the subject. A number of samples of the flour were taken and subjected to the most minute microscopic and chemical tests. The Ministry reported that the flour was good, perfectly free from all mineral impurities, and it was wholesome, sound, sweet, and normal. It had also been alleged that in the neighbourhood of Finsbury Park, London, a large number of people were suffering from dermatitis, brought about by the consumption of Chinese flour in the form of bread. The allegation was made by a medical man whose name was given, that 200, or it might have been more, of his patients were suffering from dermatitis from this cause. The Ministry of Health selected a dermatologist of distinction, who, he presumed, understood dermatitis, and who went down to the neighbourhood of Finsbury Park and saw the patients of this doctor. The dermatologist had reported that the cases examined were suffering from scabies, commonly known as the itch, a parasitic disease which could not be associated with the ingestion of any article of food. He (Lord Crawford) presumed that while these wretched patients had been suffering from this nasty complaint they had been continuing to receive treatment for some digestive trouble. The public ought not to be misled by sensational reports of this character. The real fact was that at the present moment Great Britain had got the best bread in Europe, and if his information was correct the cheapest bread in Europe as well.

HOUSE OF COMMONS.

THURSDAY, FEB. 17TH.

Pension Award Statistics.

Mr. **RENDALL** asked the Minister of Pensions whether he had published or would publish statistics tabulating pension cases and showing the numbers of pensions increased and decreased per annum and the reasons for the alterations made, the number of cases in which medical boards were overruled by the awards branch, the number of pensions stopped, and the number of claims unsuccessfully made for pensions.—Mr. **MACPHERSON** replied: During the six months ending Jan. 31st, 1921, 525,000 men were re-examined by medical boards for renewal or termination of pension, with the following results: Pensions increased, 42,600; pensions unaltered, 219,650; pensions reduced, 193,850; pensions terminated but gratuities awarded, 26,000; no further award, 13,900. During the same period 84,000 first claims were considered, and in 60,000 of these cases pension or gratuity was awarded. In reply to the second part of the question I stated that the percentage degree of disablement, on which the amount of pension is based, is in all cases determined by medical boards, whose opinion cannot be overruled by any official of this Ministry.

Pension Scale for Limb Injuries.

Mr. **RENDALL** asked the Minister of Pensions whether he was aware that the pension scale for limb injuries, which gave a stated sum as compensation for the limb lost, ignored the pensioner's general health, which might be shattered or gravely injured by the injuries that caused the loss of the limb; and what course he had taken or proposed to take to deal with this problem.—Mr. **MACPHERSON** replied: The scale contained in the First Schedule of the Royal Warrant is designed to compensate merely for the specific injuries there stated. In the actual award of pension, however, due allowance is made for any concomitant loss of health, the amount of pension being based on the total extent of disablement due to, or aggravated by, service.

Regulations under Dangerous Drugs Act.

Mr. **JOSEPH JOHNSTONE** asked the Secretary for the Home Department whether he was aware that the Draft Regulations under the Dangerous Drugs Act, 1920, were causing dissatisfaction and alarm to registered pharmacists and dispensing chemists; whether the Pharmaceutical Society of Great Britain had protested against the Regulations being further proceeded with until the whole situation had been considered by the Government Department in consultation with the Pharmaceutical Society; whether these Draft Regulations superseded the Pharmacy Acts, interfered with the reasonable liberties of the people, and involved details leading to unjustifiable expenditure; and whether he would consider the advisability of suspending the Regulations meanwhile with a view to their amendment and adjustment.—Mr. **TREVELYAN THOMSON** asked the Home Secretary if he could see his way to withdraw the Draft Regulations issued under Section 3 of the Dangerous Drugs Act, 1920, which were considered unworkable in their present form by those who would have to carry them out; and would he consult the representatives of the pharmaceutical societies in the redrafting of these Regulations so that the objects of the Act might be achieved with the minimum instead of the maximum of inconvenience to the public.—Lieutenant-Colonel **WALTER GUINNESS** asked the Home Secretary whether the new Regulations would be withdrawn and redrafted in view of the overwhelming opinion among medical practitioners that in their present form they were unnecessarily irksome, totally impracticable, and likely only to encourage the desire for dangerous drugs by notifying patients by means of a label whenever medicines contained morphine and other narcotics.—Mr. **CLOUGH** asked the Home Secretary whether he had received protests from the medical profession against the new Regulations on the ground that they would not only be useless and expensive but a source of danger; and whether he would again investigate the whole matter before enforcing these Regulations.—Sir **HARRY HOPE** asked the Home Secretary whether, in view of the strong feeling against the Dangerous Drugs Act, he would open an inquiry with the object of removing some of the hardships which the Act would entail.—Major Sir **BERTRAM FALLE** asked the Home Secretary if his attention had been called to the widepread objection to the new Regulations, and if he could make any statement.—Sir **THOMAS BRAMSDON** asked the Home Secretary if in formulating the Draft Regulations for the scale, prescribing, dispensing, and distribution of cocaine, ecgonine, morphine, heroin, and opium (medicinal), the British Medical Association, which represented and spoke for over 22,000 medical men, were not consulted; if he was aware that the proposed Draft Regulations were regarded by medical practitioners throughout the kingdom as impracticable; that if Clause 13 of the proposed Regulations be strictly carried out it would be impossible for medical men to obtain those drugs from wholesale chemists by train or through the post; and that, however urgently needed, it would be impossible for a doctor to obtain these drugs by a telephone message; and if he was prepared to submit the Regulations for consideration and amendment to a committee composed of representatives of the Home Office, the Ministry of Health, the British Medical Association, and the Pharmaceutical Society as well as the Veterinary Surgeons, as representing all the interests concerned in dealing with these drugs.—Lieutenant-Colonel Sir **JOHN HOPE** asked the Minister of Health whether the Regulations under the Dangerous Drugs Act, 1920, would prevent farmers and other horse-owners keeping colic draughts containing opium, the administering of which in cases of emergency often saved the lives of animals, especially where it was impossible to get veterinary aid quickly.—Lieutenant-Colonel **HURST** asked the Minister of Health whether he consulted the British Medical Association or the Pharmaceutical Society before issuing Draft Regulations on Jan. 7th last under the Dangerous Drugs Act; whether he was aware that transactions in morphia, cocaine, heroin, opium, and ecgonine represented roughly half the dispensing practice of a doctor, and that the records of such transactions required by the Regulations must be a burden upon all doctors in dispensing practice; and whether he would now reconsider this question having regard to professional opinion.

Sir John Baird (Under Secretary for the Home Department) replied: With the permission of the House I will make a statement covering all these questions. In the first place I desire to make it clear that the Regulations are at present in draft only, and will not come into operation until they have been formally made. They are issued first in draft for the express purpose of giving all parties interested the opportunity of expressing their views before they are finally made. The criticisms that have been directed against the Department for not having consulted this body or that before issuing the Regulations are, I think, therefore a little misplaced. Representations have been received from a number of bodies, and these are being carefully considered. Many of the objections are based on a misapprehension of the meaning of the Regulations, as, for instance, the objection to Regulation 13 referred to by Sir T. Bramsdon; and where necessary the wording of the Regulations will be amended so as to make the meaning perfectly clear. Apart from these a number of important points have been raised, and these are being, or will be, discussed with the representatives of the interests concerned. As regards the application of the Regulations to agriculture, my right honourable friend is in consultation with the Ministry of Agriculture. I may remind the House that the Regulations are proposed in order to carry out the obligations which the Government have undertaken by the International Opium Convention and the Treaty of Versailles to confine the use of the drugs in question to medical and other legitimate uses. Parliament gave express powers for the purpose in the Dangerous Drugs Act of last session. I imagine that the need for additional restrictions in view of the prevalence of the drug habit will be generally admitted. At the same time, it is not my right honourable friend's desire or intention to impose any restrictions beyond what are absolutely necessary to effect the purpose, and he hopes he may be able to meet, to a very large extent, the views which have been submitted to him. When the Regulations are finally made they will be laid before Parliament, and Parliament will have an opportunity of discussing them if it so desires.

Colonel Greig: Is it not a fact that these *Draft Regulations* have been published in accordance with an Act of Parliament which has been on the Statute Book for the last 20 years—the Rules Publication Act—in order that anyone may object or comment as he thinks fit?—Mr. Thomson: Are we to understand that the Home Secretary will receive a deputation from these various societies, and discuss with them the points that have been raised?—Sir J. Baird: The Home Secretary has already agreed to receive a deputation.—Mr. Raffan: Will the Rules become operative before the discussion which has been promised takes place in this House, or will the Minister be guided by the views of Members of this House before the Regulations assume their final form?—Sir J. Baird: The position is that the Rules have to lie on the Table of the House for 21 days, and during that period a Member of this or the other House can move an Address to the King objecting to them. It does not lie with the Government or the Minister to find time.—Mr. Raffan: They do not become operative for 21 days?—Sir J. Baird: No. —Sir D. Maclean: When does the honourable baronet think that these Regulations will be laid? Will it be in the course of the next month?—Sir J. Baird: Yes, I think certainly in the course of the next month. The matter is rather urgent, because in the event of the Treaty with Turkey being ratified the Regulations under which we can now exercise restrictions on opium and cocaine will lapse, and unless there is something to put in their place a deplorable state of affairs will be created. I am afraid I cannot give an absolute date when these Regulations will be laid or when the discussion with bodies affected will take place.—Sir J. D. Rees: Is the honourable baronet aware that these Draft Regulations are viewed with consternation by the people concerned? Is it really contemplated that the few supermen of the League of Nations are to worry every underdog about every matter like this? Will my honourable friend represent to the Home Secretary the intense unpopularity of these Regulations, which are utterly unjustifiable?—Sir J. Baird: I think my right honourable friend is aware that a certain amount of unpopularity has been aroused by them. He is doing his best to meet the objections so far as he legitimately can, having regard to our international obligations.—Mr. Acland: Is it not a fact that the International Opium Agreement was come to before the League of Nations was born or thought of?—Sir J. Baird: That is perfectly true.—Sir H. Craik: Is the honourable baronet aware that the opportunities of discussing an Order laid on the Table of the House are absolutely illusory unless the Government give time for it?—Sir J. Baird: I will not presume to argue a matter of that sort with the right honourable gentleman who has had much more experience than I have, but I believe he is in error. The Government has nothing to do with it; the House has the right to discuss the matter on any day.

Health Insurance Arrears.

Mr. William Thorne asked the Minister of Labour if he was aware that many workpeople were falling into arrears with their health insurance contributions in consequence of widespread unemployment; whether he could arrange for the labour exchange officials to be empowered to place stamps upon the cards; or whether the arrears could be remitted altogether during the present period of distress.—Dr. Macnamara replied: The out-of-work donation scheme provides for the payment by the Ministry of Labour of the health insurance contributions of persons receiving donation whilst unemployed. There is no corresponding provision in the Unemployment Insurance Act, 1920, and to pay the health contributions of persons receiving unemployment benefit would require statutory authority. The question whether arrears of health contributions could be remitted entirely during the present industrial depression is one which should be addressed to the Minister of Health.

Milk and Dairies Bill.

Mr. Swan asked the Minister of Health if he would state when it was proposed to proceed with the Milk and Dairies Bill.—Dr. Addison replied: It is not at present proposed to reintroduce the Milk and Dairies Bill during the present session.

FRIDAY, FEB. 18TH.

Dogs Protection Bill.

Sir F. Banbury introduced a Bill "to prohibit the vivisection of dogs," which was supported by Sir John Butcher, Colonel Burn, and Mr. Joseph Green. The Bill was read a first time and the second reading is down for Tuesday, April 12th.

MONDAY, FEB. 21ST.

Medical Record Cards.

Sir J. D. Rees asked the Minister of Health whether the new record cards had been dropped in view of the almost universal objection entertained to this development of social reform.—Dr. Addison replied: No, Sir. I am unaware of any grounds for the statement in the honourable Member's question that there is almost universal objection to the insurance medical record cards. From about 10,000 Approved Societies and branches I have five protests only; out of 150 Panel Committees (representing insurance practitioners), five representations mainly on points of detail; while from the Insurance Committees (which administer medical benefit in every county and county borough) I have received no protest whatever. On the contrary, one large Insurance Committee which had before it a resolution disapproving of the new medical cards, rejected the resolution by 21 votes to 2. In these circumstances, I fear that the honourable Member has been gravely misinformed.

Captain Sir Douglas Hall asked the Minister of Health if he would state what was the estimated cost per annum of the new medical records for insurance patients; and whether it approximated to the statement made by the local Medical and Panel Committee of the county palatine of Chester that, according to its information, the cost of the initial issue would run the London Hospital a year.—Dr. Addison replied: The annual cost of the records will be a small sum and certainly considerably less than that of the *old medical record cards and doctors' register cards*, both of which will be replaced by the single new permanent record card. With regard to the last statement in the question, the cost of running the London Hospital in 1919 was £221,000, whilst the total initial cost to Insurance Committees, a charge which will not recur, for filling in and sending the record cards to all the practitioners in England and Wales was estimated to cost £19,000.—Sir Douglas Hall also asked the Minister of Health whether already, under the new system of medical records of insured patients, there had been cases of patients foregoing their benefits and incurring the expense of a private doctor rather than submit to a record of their complaints being made by the panel doctor on the record cards?—Dr. Addison replied: I understand that allegations to the effect stated in the question have been made in some two or three cases only out of the millions of insured persons. I may add that the fact that medical men, Approved Societies, and Insurance Committees, as well as insured persons having first-hand knowledge of these matters, have remained quite unmoved by the recent agitation is convincing proof of its unreal character.

Maintenance of Patients in Mental Hospitals.

Mr. Finney asked the Minister of Health whether his attention had been drawn to a resolution of a meeting of Poor-law guardians of the Wolstanton and Burslem union, Staffordshire, calling attention to the increasing charges on the rates and with *special reference to the recent increase* for the charge in the maintenance of patients in the mental hospital from 28*s.* to 35*s.* per week, and to the fact that the Exchequer contributions, as fixed under the Local Government Act, 1888, remained the same, and the grant, notwithstanding the enhanced cost of maintenance, for patients in mental hospitals still remained at 4*s.* per week per patient, which grant of 4*s.* was fixed originally when the average cost of maintenance would be from 8*s.* to 9*s.* whereas it was now four times the amount, and in addition the establishment and other charges included in the precepts received by guardians from county councils increased considerably the amount of 35*s.* weekly, and protesting most strongly against these increasing burdens without some adequate or comparative increase in the amount of the grants allowed, and pressing that some definite action be taken by the Government to make some recompense and appease the indignation caused by such increasing charges on the rates; and whether he could indicate the intentions of the Government respecting the same.—Dr. ADDISON replied: I have received a copy of this resolution. As I stated in reply to numerous questions asked last session on this subject, it would not be practicable, in view of the contemplated reform of the Poor-law, to deal with this particular matter at the present time.

The Dentists Bill.

Mr. WATERSON asked the Minister of Health if he could state if it was the intention of the Government to proceed with the Dentists Bill.—Dr. ADDISON replied: I hope to be able to give a definite answer to this question this day fortnight.

Import of Salicylic Acid.

Major BARNES asked the President of the Board of Trade if an import licence for two hundredweights of salicylic acid (B.P.) required for the purpose of making medicated ointment had been refused; and if he would say in the manufacture of what dyestuffs, colours, or colouring matters salicylic acid (B.P.) was used.—Sir PHILIP LLOYD-GREAME replied: I understand from the Dyestuffs Advisory Licensing Committee that the applicants in the case referred to are being informed that, if they can satisfy the Committee that the consignment is of B.P. quality and is to be used solely for medicinal purposes, and will undertake to produce proof, if required later, that it has been so used, the Committee will be prepared to reconsider their decision.

Testing Thermometers.

Sir HERBERT NIELD asked the Parliamentary Secretary to the Ministry of Munitions whether the control and testing of thermometers formerly performed at the National Physical Laboratory and taken over by the Ministry during the war was still retained by the Ministry; if so, how many persons were engaged upon such work and at what cost; whether the work constituted a separate department and how long it was proposed to continue it; and what reason could be assigned by him for not re-transferring the work to the National Physical Laboratory.—Sir PHILIP LLOYD-GREAME (Parliamentary Secretary to the Board of Trade) replied: With regard to the first part of the question, the testing of thermometers of all kinds has always been undertaken by the National Physical Laboratory since before the war on payment of a fee. The Ministry of Munitions issued an Order in October, 1918, *for the administration of which* the Board of Trade is now responsible, making the testing of clinical thermometers compulsory. This testing, as required by the Order, is performed by the National Physical Laboratory. The remainder of the question, therefore, does not arise.

Scottish Doctors and Telephone Charges.

Mr. ALEXANDER SHAW asked the Postmaster-General whether he was aware of the hardship to medical men in various localities in Scotland who were being called upon to pay twice the previous cost or more for telephone service and were unable to bear this addition to the costs of carrying on their practice; and whether he was prepared to take any action in the matter.—Mr. ILLINGWORTH replied: I regret that a preferential tariff for the medical profession at the expense of other classes of subscribers cannot be justified, but as medical men usually originate comparatively few calls it is unlikely that the new rates will, save in exceptional cases, add as much as 100 per cent. to the cost of the service.

WEDNESDAY, FEB. 23RD.

Professional Secrecy.

Lieutenant-Colonel FREMANTLE asked the Minister of Health whether, prior to directing medical practitioners under the National Health Insurance Act to place certain confidential entries on medical history cards, he had consulted, or would consult, the law officers of the Crown as to whether the practitioners would be guilty of violation of secrecy and be liable to actions for libel if such entries were entrusted by them to private secretaries, in accordance with their usual practice.—Dr. ADDISON *replied: I am advised that in the circumstances* mentioned it is in the highest degree unlikely that there would be any cause of action against the doctor, unless he were shown to have been actuated by malice. The general question as to the position in the law of medical secrecy was submitted by me to the Lord Chancellor in June last year, and the matter which raises very important issues is being considered.

Colonel FREMANTLE asked the Minister of Health if he had obtained or would obtain the opinion of the Law Officers of the Crown as to whether subpœnas may be granted compelling the production of medical history cards in legal proceedings; and whether panel practitioners concerned in their preparation may be called upon to support the statements therein made.—Dr. ADDISON replied: I am advised that though a person may be compelled by means of a Subpœna Duces Tecum to bring any document, private or otherwise, to the court, the document itself does not thereby become admissible in evidence. A record card is, I am advised, not evidence of the facts stated in it, and, if it is desired to prove them, this must be done in the ordinary way—viz., by the oral evidence of the doctor himself.

Appointments.

Certifying Surgeons under the Factory and Workshops Acts: MCDOUGALL, D., M.B., Ch.B. Glasg. (Kilbride); ROBERTSON, I. M., M.B., Ch.B. Glasg. (Strichen).

Vacancies.

Wigan Infirmary.—Hon. P. and Asst. Hon. P.

Wilts County Council.—Female Asst. County M.O.H. and Asst. Sch. Med. Inspec. £500.

Wolverhampton and Staffordshire General Hospital.—Hon. Specialist Ear, Nose, and Throat Dept. Also Res. Cas. S. £300.

York Dispensary.—Res. M.O. £250.

York Retreat.—Med. Supt. £800-£1000.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for a Certifying Surgeons under the Factory and Workshops Acts at Hammersmith, Allendale, Eccles, Kirkby Lonsdale, Shap, and at Colne.

THE Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for the Sheriffdom of the Lothians and Peebles. Applications should be addressed to the Private Secretary, Scottish Office, Whitehall, S.W.1, and should reach him not later than March 16th.

Births, Marriages, and Deaths.

BIRTHS.

CUNNINGHAM.—On Feb. 16th, at Chesham, Bucks, the wife of F. H. Lester Cunningham, M.C., M.B., B.S. Lond., of a daughter.

HALLETT.—On Feb. 11th, at Eltham-road, Lee, S.E., the wife of Denys B. I. Hallett, M.A., M.B., B Ch. Oxon., of a son.

NIXEY.—On Feb. 20th, at St. John's-hill, S.W., the wife of E. F. W. Nixey, M.B., of a daughter.

SCOTT.—On Feb. 13th, at Sussex-square, Brighton, the wife of Dr. Evelyn D. Scott, of a daughter.

MARRIAGES.

RICHARDS—OLIVIER.—On Dec. 21st, 1920, at St. Martin's-in-the Fields, by the Rev. Dr. Oxford, M.D., William Arthur Richards, M.B., B.S. Lond., to Noel Olivier, M.B., B.S. Lond.

VINTER—PENOYRE.—On Feb. 19th, at St. George's, Bloomsbury, Noel Sydney Bailey Vinter, M.B., B.S., to Alice Dorothy, eldest daughter of the Rev. Prebendary Stallard Penoyre, Rector of Stockton, Worcester.

DEATHS.

CULLEN.—At the British Station Hospital, Jhansi, United Provinces, India, on Jan. 16th, 1921, Dr. J. A. W. Cullen, B A., M.B., B.Ch., B.A.O., District Surgeon, Great Indian Peninsula Railway.

GAMLEN.—On Feb. 18th, at Dawlish, from blood poisoning, Captain Robert Long Gamlen, M.D., B.C., D.P.H. (I.M.S., retired), in his 40th year.

TARBET.—On Feb. 15th, at Swansea, Peter Rowly Tarbet, M.R.C.S., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Friday, Feb. 25th.

CLINICAL SECTION
SECTION OF MEDICINE } at 8.30 P.M.
SECTION OF SURGERY

Adjourned Discussion:

On "The Medical and Surgical Treatment of Graves' Disease" to be reopened by Mr. Donald Armour, followed by Dr. J. M. H. Campbell, Mr. W. H. C. Romanis, Mr. A. J. Walton, Professor Earle, and others.

Monday, Feb. 28th.

SECTION OF ODONTOLOGY: at 8 P.M.

Paper:

Mr. W. W. James: Some Clinical Cases associated with Dental Infection.

Casual Communication:

Mr. P. Cole: Condition of Two Pedicle Bone Grafts Two Years after Operation (illustrated by X Ray Photographs).

Tuesday, March 1st.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Discussion:

On "Recurrent Dislocations (Shoulder, Patella, &c.) and their Treatment," to be opened by

The President (Mr. Laming Evans): On Recurrent Dislocations of the Shoulder.

Mr. W. Rowley Bristow: On Recurrent Dislocations of the Patella.

Cases: The following will be shown by—

The President: (1) Recurrent Dislocation of Shoulder; (2) Recurrent Dislocation of Patella.

Mr. T. H. Openshaw: Recurrent Dislocation of Shoulder.

Mr. O. L. Addison: Recurrent Dislocation of Patella.

Mr. W. Rowley Bristow: (1) Recurrent Dislocation of Shoulder (Bilateral); (2) Two Cases of Recurrent Dislocation of Patella.

Mr. H. A. T. Fairbank: Recurrent Bilateral Subluxation of Shoulder.

SECTION OF PATHOLOGY: at 8.30 P.M.

LABORATORY MEETING at the Bacteriological Department of Guy's Hospital, S.E.

Demonstrations:

Dr. E. P. Poulton: (1) Modification of Van Slyke's Method of Measuring Oxygen in Blood; (2) Method of obtaining Alveolar Air Samples in Untrained Persons.

Wednesday, March 2nd.

SECTION OF SURGERY: at 5.30 P.M.

Demonstration (illustrated by means of the epidiascope):

Mr. Edred M. Corner: Items of General Surgical Importance (the Fate of Silk, Nerve Regeneration, and Internal Scars) from a Surgical Backwater (Amputations).

At 4.30 P.M.:

Pathological Specimens from the Royal College of Surgeons and the St. Thomas's Hospital Museums, Skiagraphic Plates, Prints, and Illustrations will be on view.

Thursday, March 3rd.

SECTION OF OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Dr. Russell Andrews: (1) Two Cases of Sarcoma of the Uterus; (2) Lipomatosis of Stroma of a Uterine Fibromyoma.

Papers:

Dr. Geoffrey Evans: A Study of the Condition of the Arteries in a Uterus Removed 24 Days after Delivery.

Dr. Alec Bourne: Puerperal Salpingo-peritonitis.

Friday, March 4th.

SECTION OF LARYNGOLOGY: at 4 P.M.

Cases will be shown by Sir James Dundas-Grant and others.

SECTION OF ANÆSTHETICS: at 8.30 P.M.

Paper:

Mr. Raymond Apperly: The Importance of the Examination by the Anæsthetist of the Patient previous to Anæsthesia.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 28th.—8.30 P.M., Discussion on the Chemical Estimation of Gastric Function, introduced by Dr. J. H. Ryffel. Followed by Dr. J. A. Ryle, Dr. T. I. Bennett, Dr. R. L. M. Wallis, Mr. E. C. Dodds, Dr. G. Graham, Dr. C. Bolton, Dr. R. Hutchinson, and Dr. W. H. Willcox.

TUBERCULOSIS SOCIETY OF GREAT BRITAIN AND IRELAND, at Margaret-street Hospital, W.

MONDAY, Feb. 28th.—7.30 P.M., Paper:—Dr. W. Gordon: Rain-bearing Winds and Tuberculosis.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

WEDNESDAY, March 2nd.—8 P.M., Lecture:—Capt. J. M. Hollis: The Re-education of the Disabled.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Feb. 28th.—2 P.M., Mr. Baldwin: Demonstration of Cases (Surgical Wards). Dr. Morton: X Ray Department. Dr. S. Pinchin: Medical Out-patients. 5 P.M., Lecture:—Dr. G. Stewart: General Paralysis of the Insane.

TUESDAY.—2 P.M., Dr. Burnford: Medical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Skin Department. 5 P.M., Lecture:—Mr. T. Gray: Surgical Disorders of the Stomach and Duodenum.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Gibb: Eye Department. 5 P.M., Lecture:—Mr. D. Armour: Physical Signs and Diagnosis of Abdominal Tumours.

THURSDAY.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 2 P.M., Mr. B. Harman: Eye Department. Mr. D. Armour: Operations. 5 P.M., Special Lecture:—Sir Archibald Garrod: The Interaction of the Glands of Internal Secretion (open to all medical practitioners).

FRIDAY.—10 A.M., Mr. D. Buxton: Dental Department. Dr. McDougal: Electrical Department. 2.30 P.M., Dr. Pritchard: Visit to Medical Wards. 5 P.M., Lecture:—Mr. Addison: Early Hip Disease.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 28th.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M., Dr. A. J. Whiting: Medical In-patients. 2.30 P.M., Mr. E. Gillespie: Surgical Operations. Mr. J. B. Banister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Lecture:—Mr. J. B. Banister: Pyelitis in Pregnancy. 6 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

TUESDAY.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. J. Howell Evans: Selected Surgical Cases. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

WEDNESDAY.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B. Alexander: Medical Out-patients. 3 P.M., Clinical Demonstration:—Dr. W. J. Oliver: Cases of Skin Disease. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

THURSDAY.—2.30 P.M., Mr. N. Fleming: Eye Out-patients. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: *Surgical Out-patients. Mr. J. B. Banister: Gynæcological* Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Lecture:—Dr. F. L. Provis: The Modern Treatment of Syphilis.

FRIDAY.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 3 P.M., Clinical Demonstration:—Mr. E. Gillespie: Selected Surgical Cases. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

SATURDAY.—3 P.M., Mr. H. W. Carson: Surgical In-patients.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, Feb. 28th.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Kinnier Wilson: Functional Nervous Disease and its Treatment.

TUESDAY, March 1st.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Mr. Armour: Cervical Ribs, *their Symptoms and Treatment.*

THURSDAY, March 3rd.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Dr. Gordon Holmes: Muscular Atrophies. (I.)

FRIDAY, March 4th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Tooth: Lecture Room. Demonstration of Cases.

Fee for Post-Graduate Course £7 7*s*. C. M. HINDS HOWELL, Dean.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

MONDAY, Feb. 28th, AND THURSDAY.—3 P.M., Emeritus Lectures:—Dr. W. McC. Wanklyn: The Future of the Medical Profession.

FRIDAY.—3 P.M., Sir Richard Douglas Powell: The Ætiology of Phthisis.

KING'S COLLEGE (DEPARTMENT OF SCIENCE), Strand.

Nine Lectures on Problems of Modern Science.

WEDNESDAY, March 2nd.—5.15 P.M., Lecture (VII.):—Dr. R. R. Gates: Botany.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 3rd.—4 P.M., Lecture:—Dr. A. M. H. Gray: Itching in Children. (Cases will be shown.)

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

MONDAY, Feb. 28th.—5.30 P.M., Post-Graduate Lecture:—Dr. R. O. Moon: Arterio-Sclerosis.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, March 3rd.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: The Skin Eruptions of Syphilis.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

TUESDAY, March 1st.—3 P.M., Lecture:—Prof. A. Keith: Darwin's Theory of Man's Origin.

SATURDAY.—3 P.M., Lecture (I.): Sir Ernest Rutherford: Electricity and Matter.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, March 1st.—4.30 P.M., Lecture:—Dr. C. H. Melland: The Significance of the Various Signs and Symptoms of Heart Disease.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, March 3rd.—4.30 P.M., Dr. Gibson: Seborrhœic Dermatitis. (At Salford Royal Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, March 4th.—4.30 P.M., Dr. Dougal: The Diagnosis and Treatment of Tumours complicating Labour, Pregnancy, and the Puerperium.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade-lane.

SATURDAY, March 5th.—3.30 P.M., Dr. Hickling: Rickets. (At the Babies' Hospital.)

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Cmdr. A. F. Harper is placed on Retired List.

ROYAL ARMY MEDICAL CORPS.

Major T. H. Gibbon retains the temporary rank of Lieutenant-Colonel whilst specially employed.

C. B. Dyson (late Captain, Special Reserve) and R. T. G. Aickin (late temporary Captain) to be temporary Captains.

Temp. Capt. S. A. McClintock to be temporary Major whilst specially employed.

TERRITORIAL FORCE.

Lieut.-Cols. J. B. Berry (on account of ill-health) and P. R. Ash relinquish their commissions and retain the rank of Lieutenant-Colonel.

Surg.-Major R. L. Fitz-Gerald, from 5th Battalion, East Lancashire Regiment, to be Major.

Major N. Maclaren to be Lieutenant-Colonel and command 1st Western Casualty Clearing Station.

Capt. D. G. Rice-Oxley to be Lieutenant-Colonel and command 1st London (City of London) Field Ambulance.

Capts. W. Bowater, C. H. S. Redmond, and G. B. Gill to be Majors.

Capt. H. L. Garson (late R.A.M.C., S.R.) to be Captain.

Notes, Short Comments, and Answers to Correspondents.

SIR ASTLEY COOPER.

Sir Charters Symonds's Hunterian Oration, which we published last week, recalls the fact that the place of honour in the first issue of THE LANCET, dated Oct. 5th, 1823, was occupied by a report of one of Sir Astley Cooper's surgical lectures given at St. Thomas's Hospital. A paragraph introductory to the report gives some idea of the surgeon's popularity.

> At half-past seven the theatre was crowded in every part by upwards of four hundred students of the most respectable description; in fact, we never before witnessed so genteel a surgical class; the sight was most pleasing, for they all appeared gentlemen of cultivated manners and good education.

Sir Astley Cooper was then at the height of his fame; his wealth, social position, and charm of manner were added to an unrivalled surgical reputation, the latter being the result of a good memory, a vast professional experience, and a singular power of inspiring confidence in patient and student alike. He was an indefatigable dissector, and his connexion with the resurrection men only served to increase his fame in the public eye—a fame, perhaps, unrivalled before or since. His attitude towards the publicity accorded to his work by the printing of his hospital lectures—a procedure then entirely without precedent—seems at first to have wavered between wounded dignity and well-founded professional pride; in the course of his first official reference to the matter he delivered himself to his students as follows:—

> Though I did not regard the publication of my lectures I felt myself disgraced and degraded by my name for ever appearing in the diurnal press. Not a paper could I see but my name flourished in it in some form or other. This looked so much like quackery, so much like puffing, that I am unable to describe to you how much it annoyed me. Although the publication of my lectures exposes me to the critical ordeal of my professional brethren, yet I fear it not; I care not who may be made acquainted with the doctrines I advance, the instructions I give, the principles I inculcate, while in this theatre. Therefore I am perfectly indifferent as to who publishes them, and equally indifferent as to who may be made acquainted with them.

He had previously moved for an injunction to restrain further publication, but arrived at a somewhat ingenuous agreement whereby his lectures continued to appear without mention of his name. This compact was loyally kept on both sides; in the welter of legal proceedings which followed the printing of lectures by some of his colleagues Sir Astley Cooper took no part, although as the struggle for simple publicity developed into an agitation for widespread reform his own name was frequently and not unjustly spoken in connexion with the charges of nepotism levelled against the administrators of the London hospitals.

The great surgeon was a man of wide sympathies. In his youth, and as a result of the influence of Henry Cline, he developed an interest in democratic principles, but abandoned this peculiarity before it interfered with his career. Another of his experimental interests was the care of animals; he bought lame or ill-fed horses cheaply in Smithfield and doctored them at his own farm, often with great success. He had considerable self-knowledge, but did himself injustice when he claimed to have been "a good anatomist, but never ...... a good operator where delicacy was required." He was not a genius; his works are not classics, being defective in references to the writings of others, but they bear witness to his great and abiding love for his profession. His statue by Baily stands near the southern entrance of St. Paul's Cathedral; an excellent portrait of him by Lawrence is in the Royal College of Surgeons of England; and the triennial prize of £300 further commemorates the name of one of the principal figures of British surgery.

COLONIAL HEALTH REPORTS.

Gibraltar.—The estimated civil population in the city and harbour on Dec. 31st, 1919, was 17,773, as compared with 19,586 at the census of 1911. The birth-rate in 1919 was 24·81 per 1000 and the death-rate 19·82. The number of patients admitted to the Colonial Hospital was 1499, and there were 74 deaths. The number of out-patients was 7403. 510 surgical operations were performed, the number of deaths after the operation (13) being unusually small. In the Small-pox Hospital—an isolated building outside the town—22 cases of small-pox and one case of typhus fever were treated during the year. There were four deaths from small-pox. A sum of £2100 was expended from Colonial Government funds on the Tuberculosis Relief and Destitute Sick Poor Scheme, which is administered by the Sanitary Commissioners. The attendance at the Tuberculosis Dispensary was, on the whole, poor, but some 500 visits were paid to patients in their own homes. Six families have been provided with free quarters in the Sanitary Commissioners' Home, and 22 destitute men and 6 destitute women suffering from tuberculosis or other diseases were accommodated and fed. The daily average number of inmates of the Lunatic Asylum was 29·29. The total rainfall in 1919 was 37·7 inches, as compared with 36·73 inches in 1918.

Malta.—The civil population on April 1st, 1920, was estimated at 224,859, an increase of 204 on the previous year. The birth-rate for 1919-20 was 31·69 per 1000 and the death-rate 20·39. These figures compare with an average birth-rate of 31·8 and death-rate of 22·89 per 1000 for the past 10 years. The death-rate among children under 12 months was 220·42 per 1000 births, as against 244·60 in the previous year. The death-rate of children under five years was 84·95 per 1000 of the population at that age, as compared with 107·06 in 1918-19. There were 2038 marriages, as compared with 1642 in the previous 12 months. The death-rate from notifiable infectious diseases fell from 6·28 in 1918-19 to 2·56 in 1919-20, and the general state of health in the Islands may be regarded as satisfactory. Rigorous sanitary measures have succeeded in preventing the introduction of dangerous contagious diseases, such as plague, typhus, &c., and small-pox infection whenever introduced has been effectively checked. Endemic fevers have been prevalent, but mortality has been moderate. There were 110 cases of malaria. In 90 of these the disease was contracted elsewhere. The remaining 20 occurred during September–November in one locality in the vicinity of the Salt Pans at Is-Salini, and there is reason to believe that the infection was of local origin. The symptoms were those of benign tertian fever. Measures to improve the drainage at this place were undertaken, and there was no recurrence of the disease during the year. 3722 persons were successfully vaccinated during the year. The number of patients admitted into the hospitals of Malta and Gozo in 1919-20 was 3882. In addition to these 133,030 persons were attended by the district medical officers at the Government dispensaries or at their own residences. In the Lunatic Asylum there were 776 patients on March 31st, 1920, and the number of deaths in the year ending that date was 40. The inmates of the Leper Hospital on March 31st, 1920, numbered 84. The highest temperature in the shade was 100° F. at Casal Lia on July 13th, 1919, and the lowest 38·0° at Casal Zeitun on Dec. 27th. The mean temperature for the year was 64·8°. The total mean rainfall for the period April, 1919, to March, 1920, was 15·30 inches, or 5·4 inches less than that of 1918-19.

EXCESSIVE MOISTURE IN MARGARINE.

A LARGE firm of margarine importers of London and Manchester were fined £50 and 10 guineas costs at Salford for importing margarine containing an excessive quantity of moisture. The analysis showed that the samples taken by the Customs and Excise authorities contained 16·8 and 16·7 per cent. of moisture respectively, whereas the Sale of Food Act, 1899, as amended by the Butter and Margarine Act, 1907, allows only up to 16 per cent. of moisture in margarine. The margarine was made in Holland in factories over which the defendant firm had no direct control.

POST-WAR INCIDENCE OF TYPHOID FEVER.

A COMMUNICATION made by Dr. A. Chauffard to the *Académie de Médecine* at its session on Jan. 18th last, and quoted this week by our Paris correspondent, gives striking evidence of the efficacy of antityphoid inoculation practised on such a large scale during the war. The figures in this communication were derived from the statistics of the admissions to the Saint-Antoine Hospital. The statistics for the pre-war period 1912–13 are compared with those for the years 1918, 1919, and 1920. In the first period 27·5 per cent. of the males admitted were under 20 years of age, 72·5 per cent. over that age. In the second period 90 per cent. were under the age of 20, and only 10 per cent. were over that age. A convenient control test is supplied by the admissions of females, who were naturally not affected by the war-time inoculations. In this case the rates were 19 and 81 for the first period, 24·5 and 75·5 for the second. The numbers dealt with (in all 21 men and 65 women) are unfortunately too small to make the observations conclusive, but they are sufficiently important to justify further research along the same lines, and should such research confirm these results a strong case will be made out for general prophylactic inoculation of the civil population.

Erratum.—For "tabloids of alucol" on p. 172, col. 1, THE LANCET, Jan. 22nd, 1921, read "*tablets* of alucol."

E. F.—Dr. Addison recently stated in the House of Commons that after full consideration the Government had decided not to ratify the Washington Maternity Convention of December, 1919.

LIBRAR

The Arris and Gale Lecture

ON THE

CAUSE AND PREVENTION OF MYOPIA.

Delivered before the Royal College of Surgeons of England on Feb. 16th,

BY F. W. EDRIDGE-GREEN, C.B.E., M.D. DURH., F.R.C.S. ENG.,

SPECIAL EXAMINER AND ADVISER TO THE BOARD OF TRADE ON COLOUR VISION AND EYESIGHT.

WE are only concerned here with acquired myopia, and not with that due to a congenital defect, in which the axis of the eye is longer than normal, or with that due to increased refraction of the media. These causes are very rare in comparison with the acquired defect, in which, through elongation of the eyeball, the antero-posterior axis is increased and myopia induced, because the images of external objects are formed in front of the retina, a concave lens being required to bring the images on the retina.

The point to be specially considered is the production of this elongation. The older authorities favoured the view that the convergence of the eyes for near work caused pressure upon the eyeball, and in some way its elongation.

> "A tendency to myopia is caused by prolonged reading and near work."[1]
>
> "While no one doubts that near work produces near sight, observers have not been able to agree as to how it does it."[2]

Opinion is now undergoing change.

> "The theory that myopia is due to close work, aggravated by town life and badly lighted rooms, is gradually giving ground before statistics."
>
> "Arnold Lawson showed 5 per cent. higher myopia in the better lighted and ventilated school of Aldenham and St. Jude's schools."[3]
>
> "We believe that myopia is neither originated nor increased by near work."[4]

Ernest Thompson[5] gives the following figures on the incidence of myopia in Lanarkshire: urban districts, 17 per cent.; rural districts, 20·5 per cent.; mining, agricultural, and manufacturing districts, 26 per cent.

Myopia and Close Work.

Now, do facts support the hypothesis of myopia being caused by close work? Quite apart from mechanical difficulties which the convergence hypothesis presents, we find that in convergence excess, as in convergent strabismus or internal squint, myopia is not produced, and convergent strabismus is almost exclusively found in hypermetropic eyes. The detailed examination of some thousands of cases of myopia fail to convince me that in a single case myopia had been either caused or increased by the use of the eyes for near work. The requirements of the late war brought before ophthalmic surgeons connected with medical boards numerous cases of defective vision in men who had never consulted anyone for it or attended an eye hospital.

The argument is freely used that as few of the labouring classes are seen to be wearing glasses, their sight must be better than those of the professional classes. This argument is a very fallacious one, as it does not follow that because a man does not wear glasses he does not require them. The same argument applies to women, many of whom, though short-sighted, refuse to wear glasses. There is a great prejudice against wearing glasses among the labouring classes; they will not wear them if they can possibly avoid doing so. A barrister will wear glasses for the correction of a trivial defect—as, for instance, 0·25 dioptre of myopic astigmatism, whereas a dock-labourer with very high myopia of −25 dioptres will not wear them, and does not even feel the need of them. Again, many children become myopic without having used their eyes particularly for near work, especially when very young. It is very doubtful whether the use of the eyes for near work has anything to do with the production of myopia, and certainly nothing has been definitely proved. Even when the selected occupations have been given—compositor, lithographer, &c.—it will be found that the myopia was not contracted in their occupations, but that the occupation was selected because of short sight.

Causes of Myopia.

1. *Predisposing causes.*—The most common cause of myopia given by many writers is heredity, myopic parents being liable to have myopic children. This is only equivalent to stating that like breeds like, no intimation of the hereditary defect being stated. This may be a special weakness of the sclerotic to give way under pressure or to become affected by certain diseases. Again, the anatomical arrangements for preventing the distension of the eye may be defective. Rayner Batten[6] is of opinion that myopia is associated with high arterial tension in the young.

2. *Exciting causes.*—The first directly exciting causes of myopia are certain diseases, as measles, whooping-cough, and bronchitis. Whilst whooping-cough and bronchitis may produce their effects by an intermittent increase of intra-ocular pressure, measles may do this through diseases of the respiratory passages, or it may be that in measles a specific action is exerted on the sclerotic causing it to soften. The influence of measles in causing myopia is very clear and definite, and accounts for a large number of cases of non-progressive myopia. A boy may be wicket-keeper at his school and find on his return to school after an attack of measles that he has to give up cricket, not being able to see the ball at all. Numerous myopic persons were asked when the myopia was first noticed, if any increase were noticed at any time, and the occupation before, during, and after the onset or increase of myopia. It was then found that the onset or increase of myopia was associated definitely with certain occupations—namely, those involving heavy lifting in a stooping position, particularly in those who appear to take no other exercise, as, for instance, carters, who have at intervals to carry heavy weights. A boy will state that he had no trouble with his eyes until after he had left school; but in his employment, where he had continually to lift heavy boxes, he began to get more and more short-sighted. Then he will complain of a feeling of great tension in the eyes and headache after much lifting. The ordinarily given causes of myopia cannot apply in a large number of cases, as, for instance, porters, carmen, and those who do not use their eyes for near work. Again, in many of those having a sedentary occupation the form of exercise selected will be found to be one which would act in the way described, namely, boxing, wrestling, cycling, rowing, or digging. Coughing also appears to be a potent cause. A boy will state that there was nothing wrong with his eyes until he had a very bad attack of bronchitis; immediately on returning to school the master noticed that he was short-sighted and sent him to a doctor to be examined, and he was found to be myopic.

When anyone tries to lift a heavy box which is at the limit of his strength he experiences a great feeling of tension in the eyes; the fact that the intra-ocular tension has risen can be ascertained by palpating the eyes with the fingers. There is also a feeling as if fluid had been forced back into the eyes. When the eyes are closed in the dark a succession of violet-coloured circles appear to proceed from the periphery to the centre of the field of vision, break up, and then disappear. This appears to be due to a circulation of fluid in the inter-retinal space, that is to say, the space between the external limiting membrane of the retina and the pigment cells, in which the free ends of the rods and cones are situated. When a strong effort is made in the manner already described not only is this flow arrested, but a wave appears to pass outwards from the centre to the periphery accompanied by points of light.

Mechanism in the Production of Myopia.

The eye is an organ which possesses only a slight degree of distensibility; it is kept distended by the intra-ocular pressure, which by the laws of hydrostatics is equal upon every part of the inner surface of the sclerotic and cornea. The elastic tension of the sclerotic is of great importance; only when the sclerotic is not strong enough to resist the internal pressure upon it does it stretch and produce myopia. The posterior portion of the sclerotic is a weak spot, just like the inguinal ring, which will give way on undue pressure. This is particularly likely to occur when the eye is soft and growing, but under great stress appears to occur at almost any age. The ophthalmic artery, a branch of the internal carotid, enters the orbit through the optic foramen, where it lies below and lateral to the optic nerve. Both the artery and vein of the retina pass to it through the optic nerve. The superior and inferior ophthalmic veins, either separately or united in one trunk, leave the orbit through the superior orbital fissure and empty into the cavernous sinus. The lymph passages of the eye are divided into anterior and posterior. The lymph of the anterior and posterior chambers enters Schlemm's canal, and through it the anterior ciliary veins, with which it is in direct communication. The posterior lymph passages are the hyaloid canal, which has its outlet in the lymph spaces of the optic nerve, and the perichoroidal space, which finds its outlet with the vessels that pass through the sclera, especially the venæ vorticosæ; there is also the inter-retinal space, where are situated the free ends of the rods and cones of the retina, which also communicates with the lymph spaces of the optic nerve.

Priestley Smith[7] states that very little lymph escaped by the posterior channels in his experiments, but as these were made on dead eyes there was cessation of activity in the very important inter-retinal and choroidal regions. The intra-ocular pressure varies with the arterial pressure, but Henderson and Starling[8] showed that there was a control mechanism of considerable efficiency for regulating the intra-ocular pressure. Whereas the arterial pressure varied between 70 and 180 mm. of mercury in the experiments which were made, the intra-ocular pressure only varied between 23 and 40 mm. Hill and Flack[9] find that the pressure of the aqueous fluid depends primarily on the secretion pressure. The secretory cells regulate its amount, the capillary venous pressure adjusts itself to the secretion pressure, needing to be, and being, only the least degree above it in order that the circulation may continue. Obstruction of the venous return raises the capillary-venous pressure and the pressure of the aqueous fluid rises equally with the capillary-venous pressure, the capillaries being supported by the counterbalancing pressure of the aqueous fluid. Rise of arterial pressure, if it raises the capillary-venous pressure in the eye, causes a corresponding rise of aqueous fluid pressure; here again the fluid pressure counterbalances that in the capillaries. If the aqueous pressure be raised by injecting fluid under a higher pressure into the eye the capillary-venous pressure rises *pari passu* until the arterial pressure is reached; the circulation then stops, the vessels being compressed.

If the aqueous fluid be allowed to escape and the belly be squeezed, the capillary-venous vessels in the iris burst and hæmorrhage takes place into the anterior chamber, because the aqueous pressure no longer counterbalances the capillary-venous pressure. Filtration of aqueous fluid does not occur, because the pressure of the aqueous and the capillary-venous pressure are practically the same. Hill has recently measured the normal capillary pressure and finds it to be about 1·3 cm. of water. It will be noticed that the intra-ocular pressure rises both when the arterial pressure is increased and when the capillary-venous pressure is increased. Whether the eye will stretch or not when both occur together depends upon the power of the sclerotic to resist the increased pressure. When this is sufficient, myopia will not be produced. Any supposed increase of pressure caused by the muscles of the eye in convergence is very trivial compared with that caused by lifting a heavy weight.

Detachment of the Retina.

The retina corresponds to a membrane in a hydrodynamic system; it is attached only at the optic nerve and ora serrata. The choroidal vessels, lymphatics, and veins, and the important inter-retinal space, are separated by it from the vitreous. When fluid is forced into the inter-retinal space or choroidal spaces, it will detach the retina if the anterior pressure be less than the posterior pressure, so that fluid can escape by the anterior outlets. If the anterior pressure be equal to the posterior pressure, then the retina will be supported, and the only part to stretch will be the sclerotic; myopia will thus be produced, if its elasticity be insufficient to enable it to regain its former position. It will be noticed on examining a myopic eye that the enlargement corresponds to the posterior portion behind the retina. The pressure in the arteries, veins, and capillaries is always higher than the intra-ocular pressure and any adjustment by the secretory cells (or by filtration, if that hypothesis be preferred) cannot be effected instantaneously.

Compression of the Eyeball during Effort.

We can take as typical of effort causing myopia the case of a man trying to lift a heavy weight from the ground. His breath is held and the veins of his neck are seen to stand out, showing the obstruction to the flow of blood to the heart; this obstruction is aided by gravity. The remarks of Bell[10] are interesting in this connexion. He states with regard to the protective action of the orbicularis:—

> "During every violent act of expiration, whether in hearty laughter, weeping, coughing, or sneezing, the eyeball is firmly compressed by the fibres of the orbicularis, and this is a provision for supporting and defending the vascular system of the interior of the eye from a retrograde impulse communicated to the blood in the veins at that time. When we contract the chest and expel the air there is retardation of the blood in the veins of the neck and head, and in the more powerful acts of expulsion the blood not only distends the vessels, but is even regurgitated into the minute branches. Were the eye not properly compressed at that time, and a resistance given to the shock, irreparable injury might be inflicted on the delicate textures of the interior of the eye. If we separate the eyelids of a child to examine the eye while it cries and struggles with passion, by taking off the natural support to the vascular system of the eye, and means of guarding it against the rush of blood then occurring, the conjunctiva becomes suddenly filled with blood and the eyelids everted."

Darwin[11] makes several allusions to these remarks by Bell, and expresses surprise at not finding that men closed their eyes when lifting heavy weights. As a matter of fact, many people do close their eyes when making a severe effort of this kind.

It will be noticed that in lifting or coughing the heart beats more quickly and the arterial pressure is raised, thus increasing the intra-ocular pressure; there is back pressure on the veins and lymphatic outlets, which also raises the intra-ocular pressure; the eye being situated between these two pressures, the resistance of the sclerotic is opposed to the resultant increased internal pressure. The conditions are quite different from those existing in glaucoma, where pressure is more or less constant; in coughing, on the other hand, the pressure is intermittent, and, as in lifting, the lamina cribrosa is supported by the fluid pressure in the lymphatic spaces in the optic nerve. In lifting, the primary cause of increase of pressure is circulatory, which is not the case in glaucoma. The obstruction to the posterior lymphatic channels appears to be the chief cause in the production of myopia.

Production of Myopia by Various Means.

The following case illustrates the production of myopia: A man staying at a farm had to help to hold a bull which had become wild, and he had to exert his strength to the utmost; he ruptured himself, became myopic to a low degree and blind in one eye through detachment of the retina in the one afternoon; he stated that he had previously very good sight. Though such a disastrous result is fortunately very rare, this case admirably illustrates the causation of myopia, and had the increase been very slight might easily have passed unnoticed.

When it is considered that an increase of 1 mm. in the antero-posterior axis of the eye corresponds to three dioptres of myopia, it will be seen that very little stretching is necessary in order to produce a perceptible amount of myopia. Numerous cases could be given of myopia and detachment of the retina through whooping-cough. A young musician with low myopia, in indifferent health, was advised to take a rest and spend a year on a farm. He found that digging caused him great pain in the eyes, headache, and bleeding at the nose. His myopia rapidly increased, although he had no previous discomfort with his eyes in musical work.

Prevention of Myopia.

The recommendations which have been made by ophthalmic surgeons—namely, to avoid reading and writing in a stooping position, good lighting, ventilation, and other hygienic conditions—are advisable, but they do not seem to produce much effect in the prevention of myopia. Many myopes have the strongest objection to reading or writing in a stooping position. In diseases which produce myopia, such as measles and whooping-cough, special care should be taken of the eyes, particularly in those with a hereditary tendency to myopia. In measles the light should be arranged so that the child does not point its eyes downwards, and the head should be raised as much as possible. During convalescence exercises should be carefully regulated; those forms which raise intra-ocular pressure, particularly when associated with back pressure, should be avoided. It is probable that the sclerotic, like other parts of the body, can be strengthened by suitable exercises.

In the training of children in whom the eye is growing, when the coats of the eye are much softer than in the adult, those exercises which cause pressure and lead to myopia should be avoided. For instance, that exercise in which the child is prone and raises itself up and down on its hands, with its eyes pointing downwards, should be abolished. The student who takes his exercise very intermittently should particularly avoid those forms which produce increased tension in the eye, such, for instance, as riding up steep hills and bending forward when cycling, using dumb-bells and lifting heavy weights. If a rapid increase in the myopia in a short-sighted person is coincident with his cycling, the latter activity had better be given up.

Any occupation which involves heavy lifting is not suitable for a myopic. It is particularly in those who have sedentary occupations, who are not in fit physical condition, and who have a hereditary tendency to myopia, that these forms of exercise should be avoided. Careful regulation of exercises, especially in the debilitated, is necessary. There are exercises very easy for some children which can only be accomplished with great strain by others. If, for instance, a child can only with the greatest difficulty and pain in the abdomen raise itself on a bar, that exercise should be forbidden it. Exercises found to cause a feeling of pain and tension in the eyes in the child or adult should be strictly forbidden.

In conclusion, all exercises should be performed as far as possible in the erect position, with the eyes pointing forwards. The ordinary games and sports, like cricket, tennis, running, and archery, are beneficial, and do not cause myopia. Standing erect and swinging light Indian clubs is a very useful form of exercise for people with sedentary occupations. Boxing is not suitable for them; many boxers develop myopia. In myopic children special exercises can be devised so that every muscle may be developed without causing an increase in the myopia.

SOME
SEQUELS OF CONGENITAL SYPHILIS.*

BY SIR HUMPHRY ROLLESTON, K.C.B.,
M.D. CAMB., F.R.C.P. LOND.,
SENIOR PHYSICIAN, VICTORIA HOSPITAL FOR CHILDREN: EMERITUS PHYSICIAN, ST. GEORGE'S HOSPITAL.

IN opening a discussion on the diagnosis and treatment of congenital syphilis the ground to be covered is so wide that my remarks must be confined almost entirely to diagnosis, and further, omitting any reference to the more familiar manifestations, I would suggest the following points for your consideration:—

(A) The limits of the Wassermann reaction as a means of diagnosis.

(B) The influence of congenital syphilis (1) in favouring the onset of other infections; (2) in leading to changes in the endocrine glands and so indirectly to syndromes which are not necessarily specific; (3) in relation to diseases or syndromes which are not generally regarded as due to syphilis and are not obviously secondary to lesions of the endocrine glands.

(A) *The Limits of the Wassermann Reaction as a Means of Diagnosis.*

The Wassermann reaction is of course of the greatest importance in the diagnosis of congenital syphilis. McIntosh and Fildes[1] point out that a positive reaction at birth does not certainly imply the presence of syphilis, since, according to Boas, the reacting substance may have passed from the mother to the child in utero; otherwise, with certain exceptions, which hardly come into practical politics, a positive Wassermann reaction indicates the presence of living spirochætes and the need for antisyphilitic treatment. But the converse does not hold good, for the exceptions are both more numerous and real, and the practical question is in what circumstances should we hesitate to accept a negative Wassermann reaction as evidence that syphilitic infection is absent and that antiluetic treatment is entirely unnecessary? In the first place, it will be remembered that the Wassermann reaction may be negative for some weeks in a new-born infant and then become positive, just as in acquired syphilis the reaction does not become positive until about six weeks after infection. In the second place, the reaction tends to become negative about puberty, and the disappearance of a positive reaction does not mean that the patient's body is free from spirochætes; Warthin[2] has proved that spirochætes are present in a considerable proportion of patients with a negative Wassermann reaction during life, and believes that many of these are congenital in origin. At the Bellevue Hospital, New York, Symmers, Darlington, and Bittman[3] found that the Wassermann reaction was negative in 31 to 56 per cent., according to the antigen employed, of cases showing characteristic syphilitic lesion at necropsy; many of these, however, may have been obsolete. To determine in a given case whether a negative Wassermann reaction means that the infection has entirely died out or is merely latent and not causing the production of antibodies, a provocative injection of neo-salvarsan is often appealed to; and a point on which further information and discussion may be welcomed is how far this test, when the reaction becomes positive, should be relied on. Is the dose of salvarsan truly provocative, or is the interpretation of a latent Wassermann reaction in some way erroneous? The observations of Strickler, Musson, and Sidlick,[4] that intravenous injections of salvarsan into non-syphilitic patients with a previously negative Wassermann reaction are followed in more than half the cases by a positive reaction, suggest that there may be a fallacy in the conception of the provocative dose.

---

* Being introductory to a discussion on the Diagnosis and Treatment of Congenital Syphilis at a meeting of the Section for the Study of Disease in Children, Royal Society of Medicine, on Feb. 25th, 1921.

[1] McIntosh and Fildes: Syphilis from the Modern Standpoint, p. 141, 1911.

Syphilitic infection after severely damaging an organ may die down or out, and although its past effects are obvious it is no longer the active factor, for the symptoms depend on changes which are now more or less stationary. In such cases if the Wassermann reaction is negative, it might be logically argued that antisyphilitic treatment is unnecessary, therapeutic measures being needed to counteract the effect of the lesions originally due to syphilis but now responsible for the dystrophies. The conditions thus referred to are insufficiency of the glands of internal secretion and of the blood-forming organs. But is a negative Wassermann reaction of the blood to be regarded as final evidence that antisyphilitic treatment is quite unnecessary and that the possibility of further activity of spirochætes, possibly in the endocrine glands already affected, can be ignored? There are cases with the stigmata of congenital syphilis and a negative Wassermann reaction in which dystrophies and other lesions are cured by antisyphilitic treatment.

In an article on congenital syphilis in orthopædic clinics Roberts[5] records 226 cases of very various kinds, especially arthritis simulating tuberculous infection, all of which presented some evidence of congenital syphilis and responded to antisyphilitic treatment. The Wassermann reaction, however, was carried out in only 47 of the bone and joint cases, but negative results were obtained in cases with a positive family history and in some which recovered under mercury and iodide of potassium.

It therefore appears that at the present time it is impossible to accept as absolute the proposition that in the presence of syphilitic stigmata a negative blood Wassermann eliminates the possibility of existing syphilitic infection.

It is, of course, well recognised that in cerebro-spinal syphilis the Wassermann though positive in the cerebro-spinal fluid may be negative in the blood; it may be mentioned here that from examination of 214 infants and children with congenital syphilis Jeans[6] has shown that the cerebro-spinal fluid shows evidence of infection of the central nervous system in 33 per cent., or as frequently as in acquired syphilis; but in only one instance was the Wassermann reaction positive in the cerebro-spinal fluid and negative in the blood. It would be interesting to have further information about the Wassermann reaction in the cerebro-spinal fluid, as well as in the blood in cases of syphilitic disease of the pituitary. It seems reasonable to believe that syphilis of this intracranial endocrine gland might be associated with a positive reaction in the cerebro-spinal fluid and a negative reaction in the blood, and that the syphilitic origin of some cases of pituitary dystrophies, such as Fröhlich's adiposo-genital syndrome, some forms of obesity, gigantism, and diabetes insipidus, may be missed if the blood Wassermann only is investigated.

In dystrophies which may be due, in a secondary and delayed manner, to the effects of syphilis, but may equally be a legacy from the influence of other infections, on the pituitary, thyroid, testes, or other endocrine glands, the presence of a positive Wassermann reaction in the blood would be a very definite indication for antisyphilitic treatment, though it should not put into the background the obvious need for pituitary, thyroid, or some other or combined form of endocrine medication in addition. And in the absence of a positive blood Wassermann reaction the presence of stigmata of congenital syphilis should point to the advisability of antisyphilitic treatment, as was the custom in the pre-Wassermann days. But when there is an absence of these stigmata and the Wassermann reaction in the blood is negative, even after a provocative dose, does this mean that the participation of syphilis can always be so absolutely ruled out that antiluetic treatment is as unnecessary as it might appear to be illogical? Or is it better to take the view that in the absence of any evidence from the history or from physical examination of a past infection of another kind, such as severe enteric, measles, or scarlet fever, antisyphilitic treatment should be tried both with the object of benefiting the patient and as a therapeutic test to determine whether or not syphilis is in some degree responsible for the dystrophy. But it should be borne in mind that this appeal to the therapeutic test is not devoid of fallacy, for quite apart from their antisyphilitic effect the drugs may improve the patient's condition; iodides stimulate the thyroid, and so would counteract hypothyroidism however induced, and arsenic is a powerful tonic, especially to the blood-forming organs.

(B) *The Influence of Syphilis.*

(1) *Congenital syphilis as a disposing factor to other infections.*—It is important to bear this factor in mind, for otherwise in making a diagnosis the exciting cause —for example, a streptococcic or pneumococcic infection—when established may entirely put into the shade the disposing factor of congenital syphilis. An acute infection falling on a liver with the unicellular cirrhosis of congenital syphilis may imitate acute yellow atrophy. Hæmorrhagic disease of new-born infants may probably be due to several infections, and as the treatment by adrenalin is often beneficial, and as the adrenals are usually severely affected in these cases, it is not improbable that there is an acute infective adrenal insufficiency. Infants with congenital syphilis may be attacked—the term syphilis hæmorrhagica neonatorum has indeed been employed—and the adrenals are very frequently—next after the liver, it is stated—invaded by the spirochæte in congenital syphilis. Hence syphilis may reasonably be regarded as a disposing factor. But from its rarity hæmorrhagic disease of the new-born would appear to require some factor other than congenital syphilis, and it seems probable that this is bacterial infection for which the spirochætal invasion prepares the way. It is not, however, suggested that congenital syphilis usually underlies hæmorrhagic disease of the new-born.

Syphilis, by reducing resistance, paves the way to secondary infections of a chronic character, and so renders the treatment of the resulting disease more complex. Tuberculosis of lymphatic glands in a syphilitic subject may thus be explained, and perhaps also by the additional factor of hypothyroidism of syphilitic origin. Cases of this mixed infection have possibly often been unconsciously benefited by the old-fashioned application of tincture of iodine. The combination of pulmonary tuberculosis and syphilis concerns the acquired much more than the inherited disease.

(2) *The influence of syphilis in leading to lesions of the endocrine glands, and so indirectly to syndromes which are not necessarily specific.*—Opinion as to the importance of endocrine infections in the malnutrition, infantilism, and senilism seen in congenital syphilis is gaining ground. It would, indeed, be remarkable if the ductless glands escaped syphilisation. In most instances several of them are probably affected, and it must be remembered that when one endocrine gland is damaged the others tend to undergo change, and in the presence of a polyglandular insufficiency an exact diagnosis becomes more difficult. The adrenals, pituitary, and testes are the endocrine glands most often structurally damaged in congenital syphilis. Addison's disease, however, is very rarely thus caused; though no doubt minor degrees of adrenal insufficiency, or Addisonism as the French call it, as shown by want of vigour and muscular power, low blood pressure, and some pigmentation of the skin, would be not uncommonly noted if specially looked for. The pituitary, which may be invaded by continuity in syphilitic meningitis as well as by hæmic infection, appears to be more often affected in congenital than in acquired syphilis. Fröhlich's adiposo-genital dystrophy, adiposity, diabetes insipidus, and infantilism, may thus be explained: further, it may be pointed out that at a meeting of this section some four years ago Dr. F. Langmead[7] quoted three recent examples of pituitary insufficiency in congenital syphilis. Hypopituitarism probably also plays

---

[5] Roberts: Amer. Jour. Syphilis, 1919, iii., 557.

[6] Jeans, P. C.: Amer. Jour. Child. Dis., Chicago, 1919, xviii., 173.

[7] Langmead: Proc. Roy. Soc. Med., 1916–17, x. (Child. sect.), 25.

a part in a number of polyglandular syndromes; but the pituitary is only one of the endocrine glands deficiency of which is concerned with the causation of infantilism.

The condition of the testes in congenital syphilis has recently been investigated by Sir Frederick Mott,[8] who strongly suggests that not only may they be invaded by the spironeme but that chronic spirochætal intoxication may depress their vital energy. Infantilism is common in congenital syphilis, may be associated with juvenile general paralysis of the insane, and is correlated with the disappearance of the interstitial cells of the testes. The thyroid is not so often attacked by congenital syphilis as is the pituitary, and myxœdema is rare in children with congenital syphilis. Slighter degrees of thyroid insufficiency are not so uncommon. In a few instances exophthalmic goitre has been ascribed to disordered thyroid activity caused by congenital syphilis —for example, Hutinel and Stévenin[9] refer to a case improved by injections of perchloride of mercury and adrenalin.

The group of cases of *diabetes insipidus associated with infantilism* may well be regarded as a polyglandular syndrome, the diabetes insipidus being due to insufficiency of the pars intermedia and posterior lobe of the pituitary, and the infantilism either to the same lesion or to damage done to the interstitial cells of the testis, or possibly to implication of other endocrine glands. The occurrence of diabetes insipidus as a result of syphilis is well known, and its improvement after antisyphilitic treatment has been recorded (Schulmann and Desoutter[10]). It would be interesting to know what proportion of the cases of pluriglandular insufficiency causing diabetes insipidus and infantilism are due to congenital syphilis. As Parkes Weber[11] points out, two groups of polyuria in children may be recognised, viz.: (1) diabetes insipidus (without renal disease) associated with infantilism, which is less rare than (2) polyuria due to chronic interstitial nephritis with some degree of infantilism (more recently called renal dwarfism).

Obesity of endocrine origin is a complicated problem, for it may be associated with insufficiency of several individual glands or be pluriglandular in origin. Fröhlich's adiposo-genital dystrophy has been referred to as a manifestation of hypopituitarism, thyroid obesity is familiar, and so also is that due to insufficiency of the genital glands. Cushing[12] in 1912 considered the hypopituitary form to be the most frequent. These insufficiencies may be due to various factors, and among the infections congenital syphilis must be remembered. Lipodystrophic progressiva is thought to be an endocrine affection (F. P. Weber[13]), but except that thyroid medication has proved unsuccessful, and that it mainly attacks females, there does not appear to be any evidence as to the glands involved. In the 21 cases quoted by Parkes Weber the Wassermann reaction is mentioned in one instance only, in the daughter of a syphilitic father, and then was negative.

Another problem of even greater difficulty is how far, if at all, by impairing the activity of those endocrine glands—the pituitary, thyroid, parathyroid, and the thymus—that influence skeletal growth, congenital syphilis may be responsible for certain obscure diseases of bone, such as achondroplasia, osteogenesis imperfecta, oxycephaly, and cleido-cranial dysostosis. For in the first place there is but little proof that in these diseases the skeletal changes depend on endocrine disorder, though Baumel and Margarot[14] suggested that the first two are due to partial insufficiency of the anterior lobe of the pituitary; and in the second place the association of these diseases with congenital syphilis has been very seldom noted. Although the pancreas may show a diffuse syphilitic infiltration in congenital syphilis, it is remarkable that diabetes mellitus is extremely seldom, if ever, established as a sequel. It is true that the islands of Langerhans are not involved, but it would not have been surprising had they subsequently become affected. It has been urged by Hutinel that endocrine disorders due to syphilis in one generation may lead to dystrophies in the next generation, but in this event it would appear that syphilitic infection is not necessarily transmitted as well, and antisyphilitic treatment is therefore not required.

(3) *The influence of congenital syphilis in relation to various deseases which are not generally regarded as due to syphilis, and are not obviously due to lesions of the endocrine glands.*—The consideration of the diseases in this group chiefly bears on the estimation of the wide influence of syphilis and the need for early and preventive treatment, for though antisyphilitic treatment of the conditions when established may prevent further progress, a cure is beyond expectation.

Chronic interstitial nephritis in early life.—In pre-Wassermann days this condition was thought to be more closely related to congenital syphilis than it is now, though it was never regarded as solely due to this cause. Guthrie[15] (1897), Payne[16] (1900), and Sawyer[17] (1906), all supported the view that congenital syphilis was a cause of chronic interstitial nephritis. Nettleship[18] pointed out that both interstitial keratitis and chronic interstitial nephritis were commoner in girls than in boys, whereas taking 130 cases of chronic parenchymatous nephritis under the age of 13 years the incidence in boys (54 per cent.) was only slightly higher than in girls (46 per cent.); he therefore raised the question whether the female excess of chronic interstitial nephritis could be due to a larger number of girls born with syphilis. There are several ways in which congenital syphilis might be thought to lead to chronic interstitial nephritis: (*a*) The diffuse small-celled infiltration might either advance to fibrosis or while disappearing leave behind a diminished resistance which, as in the case of the liver, would enable other factors to act at a great advantage in inducing interstitial change. (*b*) The widespread arterial change due to congenital syphilis, which in extreme cases may obliterate the pulse in the limbs, might produce an arterio-sclerotic kidney. (*c*) Indirectly, by damaging the thyroid and possibly other glands of internal secretion, congenital syphilis might, after it had died out so that the Wassermann reaction had become negative, cause so much metabolic disturbance as to lead to chronic interstitial nephritis. This is perhaps rather a vague and speculative pathology, but it seems to have a bearing on the cases of renal infantilism or dwarfism associated with bony changes, described by Morley Fletcher,[19] Miller,[20] Parsons,[21] Barber,[22] D. H. Paterson,[23] and others. In these cases the Wassermann reaction in the blood was negative and so syphilis could not logically be incriminated; it is, however, possible that in some instances it may indirectly, as suggested above, have been the starting point of the renal and bone lesions, mainly through its effects on the thyroid, parathyroids, and pituitary, and of the infantilism, partly at any rate, by changes in the interstitial cells of the testes.

If there is any reason to regard a case of renal disease as syphilitic, mercurial treatment should, if employed at all, be very carefully watched, as it is often badly borne; it is indeed recommended that salvarsan preparations should be used instead.

Multilobular or *portal cirrhosis* in young children may no doubt be due to various causes other than syphilis. In the familial disease progressive lenticular degeneration S. A. K. Wilson rejected syphilis, though Homén and Yokoyama and Fischer took the opposite view. Other cases may be due to the poisons of infectious diseases, or to dietetic errors or precocious alcoholism. There certainly are cases of children with stigmata of congenital syphilis whose livers show ordinary portal cirrhosis, and in these the view may be taken that the diffuse intercellular cirrhosis has disappeared, but left behind it some vulnerability or diminished resistance of the liver, so that factors causing cirrhosis will readily produce this effect. In other words, that the cirrhosis is parasyphilitic in the sense that tabes and general paralysis of the insane were thought to be until they were shown to be due to the presence of spirochætes and examples of parenchymatous syphilis. I do not know of any demonstration of the *Spirochæta pallida* in the liver of portal cirrhosis in children, and the question arises whether or not in the absence of a positive Wassermann reaction in the blood anti-syphilitic treatment is advisable. There are two minor arguments in favour of adopting this course (1) since the advent of the Wassermann reaction the high incidence of a positive result in the cirrhosis of adults has suggested that ordinary portal cirrhosis may be a result of syphilitic infection (Symmers,[24] Letulle); and (2) that in the past a number of cases regarded as cirrhosis have recovered after antisyphilitic treatment; although this result is often regarded as evidence that the diagnosis of cirrhosis was wrong and that there really was gummatous disease of the liver, it is possible that the treatment arrested the progress of a true syphilitic portal cirrhosis. Hanot's hypertrophic biliary cirrhosis is so rare that its existence, apart from aberrant forms of portal cirrhosis, has aroused a good deal of criticism. Congenital syphilitic disease of the liver and spleen can undoubtedly imitate its clinical manifestations, but a question for discussion is whether by symbiosis or merely by weakening the vital resistance congenital syphilis may be responsible for some of the cases.

Chronic peritonitis.—Just as Letulle[25] brings forward evidence, mainly from a positive Wassermann reaction, that chronic peritonitis is frequently due to acquired syphilis, so Castex and Dell Valle[26] argue that chronic pericolitis with adhesions and peri-enteritis causing chronic abdominal symptoms or the condition described by Lane, Jackson, and Wilms is a late result of congenital syphilis, and they report cases responding to antisyphilitic treatment mainly by mercury. The pathogeny is described as complex and due to several factors; there may be defects in the intestinal walls developmental and due to endocrine glands, especially the thyroid, and in addition the adrenals damaged by syphilis, and further, the endocrine defects may through the nervous system cause intestinal stasis and so colitis and pericolitis. Chronic perivisceritis was previously regarded by the French school as syphilitic.

Anæmia.—By its effect on the blood-forming organs, in addition to its apparently hæmolytic influence, syphilis is a potent cause of anæmia in early life, and probably many forms may thus be produced. Syphilis, however, should be regarded as one only of the factors in infantile anæmia and not as an exclusive cause of any one form. Hutinel and Stévenin regard von Jaksch's anæmia pseudo-leukæmica infantum as usually, if not entirely, due to congenital syphilis, but this view would appear to be extreme. In a few cases congenital hæmolytic jaundice is associated with syphilis, and a causal relation is suggested by the known association of paroxysmal hæmoglobinuria and syphilis.

Mitral stenosis has been thought to be a malformation due to the influence of congenital syphilis, but it might also be argued that it is due to chronic endocarditis comparable to the obliterating endarteritis sometimes seen to an extreme degree in late congenital syphilis. Cowan and Fleming[27] have made out a good case for the syphilitic origin of, at any rate, some examples of combined mitral stenosis and granular kidneys. Queyrat[28] describes absence of the xiphoid appendix of the sternum as a sign of congenital syphilis and notes its frequent association with pure mitral stenosis.

Rickets.—Parrot's view that rickets is entirely due to congenital syphilis has never been accepted in this country, and at the present time is particularly, in the light of work on vitamines, unlikely to receive support; but in France it has been sustained with modifications. A. Fournier regarded rickets as a parasyphilitic affection and disposed to by syphilis, and Marfan considers that syphilis is a factor but not an exclusive factor, and gives the following characteristics of syphilitic rickets: (1) onset within four months of birth; (2) prominence of the cranial lesions, craniotabes, natiform skull, dilated veins; (3) well-marked anæmia; (4) chronic splenic enlargement. Hutinel and Stévenin associate severe rickets accompanied by anæmia with syphilis, and bring in endocrine affections as the connecting link between congenital syphilis and rickets. Thus, syphilis, by its influence on the endocrine glands and the viscera, modifies nutrition, damages the skeleton, and sensitises the bones to the true exciting factors of rickets.

Congenital malformations may occur in the subjects of congenital syphilis, and the question arises how far the intra-uterine activity of congenital syphilis is a cause of these defects. That it is not an exclusive cause everyone would agree, but it is possible that in this country the causal factor of congenital syphilis has been underestimated. Edmond Fournier[29] describes a large number of malformations in congenital syphilis.

NUTRITION IN VIENNA:

A STUDY OF THE FOOD-SUPPLY AND STATE OF NUTRITION OF THE WORKING CLASSES IN VIENNA.

BY MADGE R. GRIBBON
AND
MARGARET I. H. FERGUSON, M.A.

EVERYONE is aware that since the later years of the war the food-supply of Vienna has been inadequate for the population, and that the lower and middle classes are suffering from under-nutrition. But so far no attempt has been made to estimate the extent of this under-nutrition. Probably the most satisfactory method is to determine the energy value of the diets of various classes and to correlate this with the rate of growth of children. The present paper is an attempt to do this as regards the working classes.

It has been found, by definite measurements, that every individual expends daily a certain amount of energy in carrying on the vital processes essential to the continuance of life. In the case of a man at rest in bed, this is equivalent to about 1700 calories per day. This is his basal metabolism. Benedict has shown that in conditions of under-nutrition it may be decreased some 30 per cent., and it may, therefore, be possible for life to be maintained by a resting man on some 1200 calories per day. The performance of any muscular work, even that of sitting in a chair for, say, 16 hours, increases the expenditure of energy roughly to 2200 calories, while for 8 hours in bed, 14 hours in a chair, and 2 hours of moderate exercise an expenditure of 2500 calories is required—about 800 above the basal metabolism. In the child energy is also required for growth. The requirements for basal metabolism and for growth are fairly constant for any particular age, but those for muscular work vary enormously, depending upon the activity of the individual and upon the work done.

In the child more energy is required per unit of weight than in the adult, but the smaller size of body demands less total expenditure; and it is possible to express the energy expenditure of children of different ages in fractions of those of a man of normal size. The requirements of a family or community may thus be stated as those of so many men. The energy required is supplied in the food, and its energy value may be determined by the calorimeter. The gross energy of the food is not all available, some 10 per cent. being lost in the process of digestion; so that the supply in the food eaten should exceed the net requirements by this amount. It is generally accepted that the energy allowance of family diets should be equivalent to 3000 calories per man per day, and among the labouring classes in this country such a supply is generally obtained.

Method of Investigation.

To undertake the present investigation one of us (M. G.) was seconded from her work in Glasgow under the Medical Research Council, and, through the kindness of the Friends' Relief Mission, was enabled to make a detailed study of the diets of 49 families of the poorer classes in Vienna. These included 253 individuals —49 men, 65 women, and 139 children under 14 years. These studies were carried out by the methods devised by Atwater, used extensively in America, and employed in this country for the study of the dietaries of the labouring classes in Edinburgh and Glasgow. A description of the method will be found in Professor Noel Paton's Introduction to Miss Lindsay's Report on the Food of the Glasgow Labouring Classes in 1911. One of us (M. F.) is responsible for working up the results so obtained; the other (M. G.), in making the investigations, also weighed and measured the children in nearly every family, and usually ascertained the heights of the parents.

Owing to the prevalence of rickets in Vienna, the opportunity presented itself for making comparative studies of the diets of families containing children suffering from this disease, and of those with children free from the condition.

The points dealt with are: (1) the energy intake of the diet; (2) the height and weight of the children; (3) the income and expenditure upon food; (4) the composition of the diets—i.e., the actual foodstuffs used; (5) the nature and extent of the Mission help; and (6) rickets—a comparison of the two sets of dietaries.

1. *Energy Intake of the Diet.*

In determining the energy value of the food eaten Atwater's analyses were generally used. For meat the analyses of lean or "very lean" meats were selected. The results in all probability are too high, since the cattle are very emaciated, and the flour, milled to a high grade, is of bad quality. Lusk's coefficients were used in calculating the "man-value" of the families as follows:—

Man	1·0	Child, 10-13...	0·83
Woman	0·83	Child, 6-10...	0·6
Boys, 13-20	1·0	Child under 6	0·5
Girls, 13-20	0·83		

Using these coefficients the average dietary yield expressed as per man per day of all the families was:—

Energy	2064 calories.
Protein—(a) total...	64·0 g.
" (b) from animal sources	5·3 g.
Fat	40·2 g.

Since margarine was the chief source of fat it is impossible to give the amounts of fat from animal and vegetable sources. The above dietary yield is equivalent to a supply of *available* energy of about 1860 calories, an amount insufficient to meet the energy requirements of a man doing practically no muscular work, even upon the reduced basal metabolism of under-nutrition.

The variations are naturally very great alike in energy value, in proteins, and in fat. The energy value varies from 1269 to 3746 calories, or, leaving out two diets which are more than 600 calories greater than the others, from 1269 to 2941 calories; the protein intake from 38·7 to 114·7 g., and the fat intake from 12·4 to 79·6 g. per man per day. The most generous diet is that procured by a German family. It is more varied than any of the others, including fresh milk, pork, and sugar, in addition to the usual bread, vegetables, cocoa, and margarine. The other dietary over 3000 calories is made up of few foodstuffs, but these in generous amounts. Of the family having the lowest diet little information is available, but both parents are described as careless, lazy, and very undernourished. The only child (2½ years) is very deformed by rickets and not yet walking. As most of the fat consumed comes from relief agencies the extremes of fat intake show that unusually large or unusually small amounts of margarine had been received from them. The family having only 12·4 g. of fat per man per day had received only one Mission ration, among a family of five, while the family having 79·6 g. per man per day had three rations for two persons, and the amount is quite exceptionally high.

The detailed information regarding energy intake, &c., is contained in Table I.:—

2. *Height and Weight.*

The Viennese, being chiefly of Teutonic origin, belong to one of the taller of the European races. In the families investigated the father's height, ascertained in 27 cases, averaged 2·4 per cent., and the mother's height, from 41 cases, averaged 3 per cent. above the standard of the Anthropometric Committee of the British Association. Since the height of the parents approximated so closely to the British standard, it has been used to measure the growth and state of nutrition of the children. The results have been embodied in Table II.

TABLE II.—*Average Height and Weight of Viennese Children at Different Ages, compared with the British Anthropometric Standard Average (Sexes Combined).*

Age in years.	No. of children.	Weight.		Height.	
		Pounds.	Percentage under anthropo. average.	Inches.	Percentage under anthropo. average.
1- 2	7	19·6	14·8	28·5	6·6
2- 3	12	20·9	23·7	28·5	13·6
3- 4	11	21·9	29·6	30·68	15·8
4- 5	13	29·4	16·0	34·0	11·2
5- 6	14	33·7	12·8	36·21	11·5
6- 7	11	37·5	10·7	38·82	11·2
7- 8	10	39·7	14·6	43·4	4·0
8- 9	6	42·5	15·8	47·2	+0·9
9-10	8	49·8	9·3	48·69	1·0
10-11	7	50·8	17·4	50·79	1·7
11-12	—	—	—	—	—
12-13	9	62·2	14·8	53·89	2·6
13-14	5	69·6	14·1	56·1	2·0

In spite of the small numbers under each year the average percentage deficiency shows less variation than might have been expected. Taking the figures in longer periods, they give the following results :—

	Average percentage deficiency in weight.
Under 2 years (17)	15·6*
2 to 3 years (23)	26·5
4 to 9 years (62)	13·2
10 to 13 years (21)	15·5

* Including infants under 1 year not included in last table.

Comparing those between 5 and 11 with the children from one-roomed homes in Glasgow, they are at least 3½ lb. lighter.

The insufficient diet is thus associated with marked decrease in growth, the deficiency of weight, as usual, being more marked than that of height. Both height and weight are most markedly below the normal up to the age of 4 years. This is to be expected, since the normal increment during these years is greater than it is at any age up to 11 or 12 years, and the percentage increase is greater than at any subsequent period. The children of 2 and 3 years have suffered more than the infants. This is probably due to the latter having been generally breast-fed, while during succeeding years the lack of cow's milk has been most acutely felt.

The problem is—How do these children manage to grow? The diet generally allowed to children yields ample energy, not merely for basal metabolism and growth, but also for muscular exercise, which in the case of an active child may more than double the basal metabolism. Under-nutrition may not only lower the basal metabolism, but may be accompanied by decreased activity, so that the energy required for growth may still be obtained from an inadequate diet.

3. *Income and Expenditure.*

The average income of the 49 families was 466 kronen per week. Comparing the relative cost of living in Vienna and in Britain, this is equivalent to only about 12 or 13 shillings. The greater part of the income was, of course, spent on food. In 31 families, in which a detailed study was made of the expenditure, 71·2 per cent. went on food. Rents are very low, only amounting to 3·9 per cent. of the income. On the other hand, coal, wood, and petroleum are almost prohibitive in price, coal costing anything up to 6 kronen per kilo, and matches costing most families more than rent. Heating and lighting accounted for 19·7 per cent. of income. These four items of expenditure—food, rent, light, and heat—thus averaged 94·8 per cent. of income. The remainder is totally inadequate to provide for other necessities. Cloth, whether for wearing apparel or hospital bandages, is exceedingly scarce and consequently very expensive. Most of the children in the families visited were poorly and insufficiently clad.

4. *Nature of the Food Material Consumed.*

While there is an all-round shortage of food materials, meat, fats, sugar, and milk are almost unobtainable. Most of the budgets included a small amount, about 125 g. of pork, horsemeat, or sausage during the week of study, and only ten had fresh milk, though most procured condensed milk from the Friends' Relief Mission. The following is a typical diet for one week:—

Family E.—Father, Mother, Girl (4 Years), Boy (3 Years).

Income 200 kronen, plus 100 kronen from sale of a table= 300 kronen.

	Food.	Weight in grms.	Calories.	Cost in kronen.		Food.	Weight in grms.	Calories.	Cost in kronen.
A	Potatoes ...	7000	29280	100	B	Rice	500	9400	128
	Flour	2000		25		Condensed milk (unsweetened)	1642		
	Margarine..	100		10		Margarine...	250		
	Marrow ...	1000		8		Cocoa	200		
	Cabbage ...	500		2		Flour	500		
	Lettuce ...	1000		4					
	Bread... ...	6000		36					
						Total			313

A = Purchased in the market.
B = Supplied by the Friends' Relief Mission.

In addition to this two of the family had a free meal each day from the Dutch Mission. This was approximately equal to an additional 8000 calories—in all, 46,680.

5. *Nature and Extent of Help Given by Relief Agencies.*

In the budget just quoted rice, condensed milk, margarine, cocoa, and flour constitute two rations from the Friends' Relief Mission. The food composing this ration varies a little from week to week, but is practically constant in energy value—about 4700 calories. The price charged for each ration was 68 kronen, but in exceptional cases it is either given gratis or at a reduced cost. This ration may be purchased for each child in a family, but more than two rations for three children were rarely purchased.

A number of the families had food from the American or Dutch Missions instead of, or in addition to, the Friends' ration; this takes the form of a daily meal, of energy value approximately 670 calories, which was included in calculating the energy value of the diets.

Without the help of the relief agencies the diet of most of the families would have been poorer by 500 or 600 calories per man per day, averaging only about 1574 calories, and would have lacked almost entirely milk, sugar, and fats.

6. *Rickets.*

In 29 of the 49 families some at least of the children had rickets. The older children in some cases must have suffered from it before the war, as they show the characteristic deformities and were late in learning to walk. In most of the families, however, it is said to have developed within the last year or two. In every family with rickets the younger members had the disease at the active stage. Many of them presented marked deformity.

In Table I. the results of the investigation have been averaged in two groups, according to the presence or absence of rickets. The energy value of the diet of the families with rickets is 440 calories per man per day below that of those without it. The protein intake is 13·2 g. less. The families without rickets had, on the average, 3·3 g. per man per day more of protein from animal sources than the others. The difference between the two sets is mainly due to a greater shortage of flour, bread, and vegetables in the diets of the families with rickets. There was little difference in the average amount of fat consumed. A few of the children with rickets were having cod-liver oil from the Friends' Mission, but not in sufficient amount to make any appreciable difference upon the average.

Conclusion.

These studies show how very inadequate is the diet of the working classes in Vienna at the present time. Were it not for the generosity and devotion of the Society of Friends and the American and Dutch Missions, their condition would be one of actual starvation. It is hopeless to expect from a population on such diets the initiative and vigour by which alone the country can be saved from ruin.

We desire to express our sincere thanks to the Society of Friends' Relief Mission who have made this investigation possible and have helped in every way. We would also thank Professor Noël Paton for assistance in the preparation of the paper, and Miss Tully, who has aided us in drawing up tables and in working out results. We have further to acknowledge our indebtedness to the Medical Research Council for enabling one of us (M. G.) to carry on these investigations.

We hope to deal in a future paper with the dietary conditions of middle-class families in Vienna and with those of the rural population in the neighbourhood of the city.

THE BACTERIOLOGICAL INVESTIGATION OF A CASE OF PLAGUE.

BY V. M. SYNGE, M.D. DUB., D.P.H.,
PATHOLOGIST, SIR PATRICK DUN'S HOSPITAL, DUBLIN;
AND
JOSEPH W. BIGGER, M.D. DUB., D.P.H.,
MEDICAL INSPECTOR, LOCAL GOVERNMENT BOARD, IRELAND.

THE occurrence of plague in a patient who resided within about a quarter of a mile of the docks, but had no connexion with shipping or sailors, is unusual. The locality in which she resided has been free from plague both before and after her infection. On account of the rarity of this disease in such a subject, it has been thought advisable to record not only the clinical findings but also the bacteriological investigations which definitely proved the disease to be bubonic plague.

A female, aged 25, was admitted to Sir Patrick Dun's Hospital, Dublin, on Oct. 12th, 1920, with a swelling in the groin, about the size of a walnut, and a history of intense pain in that region for three days. Her temperature on admission was 104° F. and she appeared to be very seriously ill. Sir Arthur Ball removed the gland which was the cause of the swelling, and sent it for bacteriological examination to one of us (V. M. S.), by whom a tentative diagnosis of plague was made. The diagnosis was definitely confirmed a week later.

The patient then came under the care of Dr. H. Drury. Her temperature remained elevated (103° to 104·4° F.) until the sixth day of the disease, when it commenced to fall steadily, but subsequently rose again on the eleventh day. Two days later it became normal. The patient made a good recovery and was discharged from hospital on the fortieth day from the beginning of her illness.

Plague Bacillus in its Various Forms, as seen in Direct Films and after Culture.

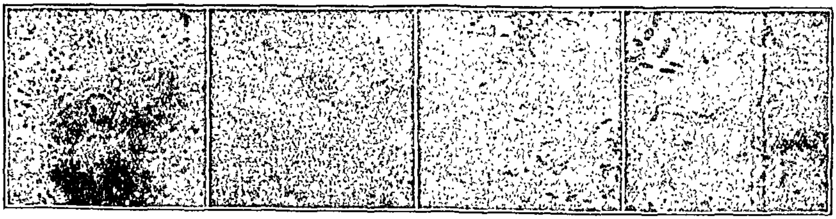

FIG. 1.—Smear from patient's gland.

FIG. 2.—Smear from guinea-pig's gland.

FIG. 3.—24-hour agar culture.

FIG. 4.—Involution forms, 72-hour culture on salt agar.

Appearance of the patient's gland.—The gland, which measured 1¼ by 1 in., was very hæmorrhagic. Films made from scrapings taken from it revealed enormous numbers of bacilli, the characteristics of which will be described later. Sections of the gland showed congestion and hæmorrhages, with some necrosis. In every part the same bacilli were present in large numbers.

Cultural characteristics of the organism isolated from the gland.—The original cultures from the gland were made on blood-agar plates. At the end of 24 hours very minute colonies, scarcely visible to the naked eye, had appeared. After 48 hours' growth the colonies measured about 0·5 mm. in diameter. The colonies were circular and raised; their surface was smooth and shining; they were of a greyish-white colour when seen by reflected light; by transmitted light they appeared slightly granular and opaque in the centre; their margins, seen with a lens, were almost transparent and had a wavy edge. Subcultures attempted from the original plates on trypagar without the addition of blood were, with one exception, unsuccessful, but a good growth was obtained on blood agar. Subsequent subcultures were uniformly successful on trypagar without blood. On agar slopes the organism gave a thick, opaque, smooth, and moist growth of a greyish-white colour. The culture was sticky and tenacious when touched with a platinum loop. On broth the organism grew slowly and formed a granular deposit at the bottom of the tube, leaving the upper part clear. On litmus milk after four days a slight acidity was produced. Gelatin was nót liquefied.

Microscopic Appearance of the Organism.

Films made from scrapings of the patient's gland showed very large numbers of short, plump, Gram-negative bacilli with rounded ends (Fig. 1). Their average size was 2·5 by 1·7 μ, and they therefore appeared almost like oval cocci. A few longer forms were also present. The most striking feature about the bacilli was that their bodies were lightly stained, with dark staining dots at either end. The bacilli in young culture (24 hours old) resembled those present in the gland fairly closely, but for the most part they were slightly longer and less plump (Fig. 3). After 48 hours' growth the bacilli appeared definitely longer and thinner, and a few quite long forms, 10 to 12 μ, were present. Polar staining was never so well marked in the bacilli from cultures as in those from the gland, but it could almost always be demonstrated. In broth culture the bacilli were only slightly longer than those from the gland. They occurred in chains of four or five members, but a few longer chains of about ten bacilli were seen. On salt agar (3 per cent. of salt) in 24 hours the bacilli were considerably larger than on plain agar. After three days' growth involution forms, oval, globular, and pyriform bodies, which took stain badly, were seen (Fig. 4). These were very much larger than the bacilli grown on other media. The organism was non-motile and spores were not present.

Experiments on Animals.

A guinea-pig was inoculated, intraperitoneally, with a culture of the bacillus. As the animal appeared to be very sick it was killed at the end of 48 hours. There was a general subcutaneous œdema of a gelatinous appearance. General peritonitis was present, and the pus from the peritoneal cavity was sticky and could be pulled out in long threads. Microscopically this pus was found to contain large numbers of bacilli resembling those found in the patient's gland but slightly longer (Fig. 2). Cultures made from the peritoneal pus and from the spleen gave an organism identical with that already described.

A second guinea-pig, inoculated subcutaneously near the knee with an emulsion of the patient's gland, died on the seventh day. A general œdema with areas of congestion was present. There was, in the inguinal region on the inoculated side, an enormous mass of enlarged glands surrounded by an area of congestion with hæmorrhages. The other glands of the body were enlarged, but not so markedly. The spleen was about four times the normal size and was studded with small white nodules about 0·5 mm. in diameter. The lungs were congested. Films made from the enlarged glands and from the spleen showed bacilli resembling very closely those present in the gland removed from the patient. The same bacillus was found in cultures made from the affected glands, the spleen, and the heart blood.

The hair on the abdomen of a third guinea-pig was shav
and a small amount of the culture of the bacillus was
on the shaved area. This animal died on the nith
The skin where the culture had been rubbed was re

rough, and there was an area of congestion with some hæmorrhages underlying it. There was a general, subcutaneous, hæmorrhagic, and gelatinous œdema. The hæmorrhages were most common in the region of the inguinal glands, which were enlarged and congested. Films made from these glands showed that they were packed with bacilli, identical in microscopic characteristics with those already described. Cultures made from the glands, the spleen, and the blood all gave growth of the same organism.

Blood Culture.

A culture of the patient's blood was made on the seventh day of the disease and a growth of the organism described above was obtained. Films made at the same time were examined, but no bacilli were found in them. Positive blood cultures are rare in plague, except in those cases which are very severe and which usually have a fatal termination.

Agglutination.

The patient's serum was tested on the seventh day of her illness to ascertain if agglutinin for *B. pestis* was present. The organism used was one obtained from the National Collection of Type Cultures, and was marked "Strain—Parel." No agglutination occurred in a dilution of 1/10. On the fortieth day a further test was made. It was then found that the patient's serum agglutinated both the type strain of *B. pestis* and the homologous organism to the same degree. With both complete agglutination was present in a dilution of 1/20, but was absent in a dilution of 1/40. The macroscopic method was used, and the tubes were incubated in a water-bath at 55° C. for four hours.

Remarks.

There can be no doubt that the organism was a true *B. pestis* and that the patient was suffering from bubonic plague. The method of infection is unknown. Both the municipal and port sanitary authorities failed to find any unusual mortality among rats. A number of rats were killed and sent to us for examination, but all were healthy. The fact that the patient owned a cat which alternately went on hunting expeditions and slept on her bed, may possibly be a link in the chain of infection. Nearly five months have now elapsed since the occurrence of this case, and no further cases have been recorded.

We have to thank Professor Adrian Stokes for the micro-photographs which accompany this paper.

THE INFLUENCE OF AERATION ON THE STABILITY OF THE ANTISCORBUTIC FACTOR.

BY S. S. ZILVA, D.SC., PH.D., F.I.C.,

ASSISTANT, BIOCHEMICAL DEPARTMENT, LISTER INSTITUTE.

THIS preliminary note describes the results obtained from some experiments instituted with the object of studying the influence of air on the antiscorbutic factor at ordinary temperature as well as at 100°C. The inquiry was pursued as an outcome from observations made that ozone inactivated this and the fat-soluble factors at ordinary temperature. The experiments revealed that bubbling air at ordinary temperature through an antiscorbutic solution inactivated it. It was found, on the other hand, that on boiling an active solution for two hours in an atmosphere of CO_2 no marked diminution in the activity could be recorded, whilst on boiling a similar solution for one hour during which time air was bubbled through almost the entire activity was lost.

These results are in conformity with the observations made by Delf (1920).[1] Miss Delf found that quite marked antiscorbutic potency was retained by orange-juice and swede-juice heated for some time at temperatures above 100° C., and she suggested that the destruction may have been affected directly either by retarded oxidation (the juice having been heated in an autoclave) or indirectly by the production of stabilising bodies. My experiments seem to point to the fact that the former is the more likely explanation for this somewhat unexpected stability observed by her in the case of the juices.

As a source for the antiscorbutic factor lemon-juice from which the organic acids were removed by precipitation with calcium carbonate was employed. The minimum dose of this solution for the guinea-pig is about 1½–2 c.cm. When air was aspirated through such a solution for 12 hours at laboratory temperature daily doses of 3 c.cm. and 5 c.cm. were insufficient to prevent, but delayed very slightly, scurvy in guinea-pigs, whilst 7 c.cm. was found to be inadequate to promote normal growth. Daily doses of 1½ c.cm., 3 c.cm., and 6 c.cm. of the decitrated juice which was boiled for one hour and through which air was bubbled during the boiling were insufficient to prevent or to delay to any very marked degree the onset of scurvy in the animals. From the administration of daily doses of 1·5 c.cm., 4 c.cm., and 6 c.cm. of the juice boiled in an atmosphere of CO_2 for two hours no inactivation which would become manifest by our present technique could be established.

It is of interest to note that the behaviour of the antiscorbutic factor towards heat and aeration is very similar to that of the fat-soluble factor. The antineuritic factor, however, seems to be more stable towards oxidation. Results obtained by exposing the antineuritic factor to ozone show that it is only affected, if at all, to an extremely small extent by that treatment.

All the data available in connexion with the behaviour of the antiscorbutic and the fat-soluble factors at high temperatures will have to be reconsidered in view of the latest results obtained as regards their great tendency to be inactivated on aeration, especially when heated.

I am indebted to Professor Sensho Hata for help in some of the experiments of this inquiry.

The expenses of this research were defrayed from a grant made by the Medical Research Council, to whom my thanks are due.

MENTAL TESTS.[1]

BY W. A. POTTS, M.A., M.D. EDIN. & BIRM.,

MEDICAL OFFICER TO THE BIRMINGHAM COMMITTEE FOR THE CAR
OF THE MENTALLY DEFECTIVE; PSYCHOLOGICAL EXPERT TO
THE BIRMINGHAM JUSTICES.

THE passing of the Mental Deficiency Act in 1913 put us ahead of every other country in practical arrangements for dealing with mental defect. The application of that Act, however, leaves much to be desired, while we are a little backward in some of the scientific work connected with it. For instance, the subject of mental tests has received but scant notice in most of our recent books, while for our test material we still have to send to Chicago. It is true that important investigations with tests have been carried out by Dr. A. R. Abelson and Mr. Cyril Burt, and recently Dr. W. B. Drummond, Mr. Ballard, and others, but as a rule the subject has been shelved. Possibly some of the tests I shall mention are crude and imperfect, but when modified they will be very valuable. In diagnosing mental capacity mental tests should be to the psychologist what the stethoscope, hæmocytometer, sphygmomanometer, and other instruments of precision are to the clinical physician; the man of experience with keen intuition can sometimes dispense with them, but even he will often find they shorten his labour, give him more definite information, and sometimes further insight. Just as the ordinary clinical instruments may fail when we need their help most, so mental tests may disappoint us in our most difficult case; but in the other 99 per cent. they are a real help. The subject opens up a vast vista of possibilities; already there are tests for vocations and particular kinds of work, and even for morals. As a matter of fact I have found moral tests distinctly useful in dealing with abnormal conduct. The psychologist, the criminologist, the educationist and all those who organise or profit by the labour of others can scarcely afford to dispense with tests. Experiments by large firms in America have shown the importance of properly arranged tests not only in selecting employees, but also in placing them straight away in those departments where they can be most useful.

---

[1] Delf (1920), Biochem. Journ., xiv., 211.

[1] Paper read at the Section of Psychiatry of the Royal Society of Medicine on Feb. 8th, 1921.

Mental tests are particularly useful in criminal work. It is true that there is no perfect set of tests for mental deficiency available; the final decision must be the judgment of the expert examiner; this is based largely in the extreme case on the conduct and mode of life of the prisoner, which must not only be abnormal, but abnormal in a manner characteristic of mental defect. Yet the legal mind finds it difficult to realise that the mental defective, particularly the high-grade one, may have nothing abnormal in his appearance, or even in his manner and conversation at an ordinary interview. It is therefore an advantage for the medical-psychologist to be able to say that in addition to his opinion based on an observation of the accused and a study of his records, he can state that the prisoner, when submitted to one series after another of mental tests which can be accomplished by ordinary people, failed, and revealed that he had a degree of intelligence only equal to that of an average child of say 8 years and 3 months. In some cases it is not failure or success in a particular test which impresses us so much as the method of approaching and carrying it out, or the degree of satisfaction with the result. The intelligent man who fails in a simple test may say at once, "What a fool I am," but the defective will often start arguing that he is right, or else smile the beautiful bland smile of absolute ignorance.

Mental Tests in the American Army.

One of the strongest arguments for tests comes from the American Army. Dr. V. V. Anderson, of the Municipal Court at Boston, U.S.A., first states that 10 per cent. of all civilian prisoners are mentally defective, and that those 10 per cent. are responsible for 50 per cent. of all crime. When the Americans came into the war they decided to raise an army of 3,000,000 men. On inquiry into the arrangements necessary for an army of that size, they were informed that experience in previous wars showed that provision must be made in military prisons for 50,000 cases. It occurred, however, to their psychologists that this number might be reduced if all recruits were given a special examination with the object of excluding mental defectives. This was done, with the result that there never were as many as 5000 cases in the American military prisons, or less than one-tenth of the number they expected to have. The American psychologists, however, did more than that. They extended their examination so that they analysed the intellectual capacity of the men, and so could estimate what work they were fit for in the army. Having previously found out what amount of intelligence was necessary for any particular line, they were able to point out the man best suited for promotion to commissioned work, or for undertaking work requiring special skill. They also saw that each unit had an adequate number of men with more than average intelligence, instead of allowing an accumulation of such men in one place, with a corresponding lack of capable men elsewhere. Not only did they make the best use of their good material and prevent the bad from being a handicap, but they actually made use of many of their defectives by enrolling them in labour battalions and putting them to simple tasks which they could do as well as any one else. The story recorded in "Mental Tests in the American Army, by Yoakum and Yerkes" is a marked contrast to the haphazard method adopted by our War Office, who at the beginning of the war had in the trenches highly trained mechanics, urgently required for skilled work at home, whose loss never could have been made good had there not been a reserve in America, and had not the United States recognised that they must not risk their technical experts. Of course, the methods of examination for our army were much more satisfactory towards the end of the war. In the case of the Flying Corps, at all events, the examination for admission was thorough and satisfactory. The Americans claim that the example of their army in the war must not be forgotten, because not only will the country which studies what particular qualities are required for each bit of army work, and then devises tests by which those qualities may be recognised, have an army far superior to any other in the next war, but in the industrial war of the near future that nation will have a corresponding advantage which first estimates the capacities required in any particular place, and then puts there only those who have those capacities, and does not call on the less intelligent to do work they never can accomplish. Many of the American army tests are open to criticism, so it is important to remember that the mental age was first estimated by the Terman Revision or Point-Yerkes scale, and that the other tests were often only used to elicit capacity for special kinds of work. One obvious criticism is that other factors, such as temperament and health, must also be taken into account. There are no tests for temperament yet, but that is no reason why they should not be discovered. We have made a start with morals, and even now health and other important factors besides intellect can be graded more or less satisfactorily. No system will ever meet every case, but in the mass the possibility of error is small. An important matter is to make sure the person examined does his best. As regards the actual tests, I shall only explain and demonstrate a few with the object of showing some of the different lines available for investigation.

The Graded Tests of Binet and Simon.

The first really useful set of tests we owe to Binet and Simon, who produced their original series of graded tests in 1908, and revised them in 1911. These tests enable a rapid psychological analysis to be made of certain capacities, so that the degree of intelligence may be estimated. Their great value depends upon the fact that they are arranged in a series according to age, and also that each response is either a pass or a failure. For each year of life from 3 to 10, and again, for 12, 14, and 16, there are four or five questions or tasks. These are so arranged that an average child can just pass those for his own age, but not those for later years. In actual practice it may be found that a child can accomplish some of the tests for years above that in which he has passed all. In this case his mental age is recorded as that for which he passes all the tests, with the addition of so many months, according to the number of tests for the particular year, for each one he can pass in those for higher years. These additions as a rule do not amount to much; the greatest irregularity occurs in the case of epileptics and moral imbeciles, and is, to some extent, pathognomonic of those conditions. For instance, a mentally defective epileptic youth of 18, who could not read, passed all the tests (Terman Revision) for year 6, four for year 7, five for year 8, three for year 9, three for year 10, and almost succeeded in one for year 12. His mental age was, therefore, 8½ years. Mental defect is considered to be backwardness to the extent of two years or more in a child under 9 years of age, and three years or more if over 9. It is generally agreed that a mental age of 7 years or less constitutes an imbecile.

Revisions and Modifications.

An enormous amount of work has been done on these lines, particularly in America. It was soon found that the tests were not perfect, and required modifications, especially for English children. The first revision—one that has been and is still extensively used—was put forward by Dr. H. H. Goddard, who restandardised the tests. The Yerkes-Bridges "Point Scale" altered the scoring and added new questions. Then came Professor Terman's Stanford Revision, which, in my opinion, is the best now available. In order to use these tests properly it is necessary to get Professor Stanford's book and carefully study the directions given in connexion with individual tests. If this is done, anyone who can get on with children and is able to put them at their ease can, with care and practice, learn how to conduct the examination satisfactorily. As a rule children must be encouraged in every possible way during the examination and told they are doing well;

but sometimes, as in the test with the pictures, this must not be done, because it would have the effect of making the child think his reply in regard to the first picture was quite satisfactory, when really it was not. He might, therefore, not give a better reply in the case of the two other pictures, although well able to do so.

The most recent criticism was made in the *Training School Bulletin* for March and April, 1920, by S. D. Porteous, who deals with the Terman Revision, and incidentally gives a list of the eight tests in which defectives most frequently fail. He, however, uses these eight tests as a means of confirmatory diagnosis in doubtful cases, on the grounds that if the subject shows the characteristic failures of defectives the presumption of feeble-mindedness is thereby increased. At the same time he makes this a rough-and-ready test for mental age by allowing one year for each success, beginning to count from six. Thus one success makes it six years, two successes seven years, and so on. The actual tests selected by Dr. Porteous are Test 3 for year five, Test 2 for year seven, Test 1 for year eight, Tests 2 and 4 for year nine, Tests 3 and 6 for year ten, and Test 1 for year 12.

The Intelligence Quotient.

In connexion with the mental age the term "intelligence quotient" (often designated I.Q.) is frequently used; this is the ratio of mental age to chronological age. Thus a child of 10 with a mental age of 10 is normal, and has an intelligence quotient of 1·0; but if his mental age is only 7, his intelligence quotient is 0·7. Intelligence quotients appear to remain fairly constant and therefore give a valuable guide. If a 4 years old child has a mental age of 3 his intelligence quotient is 0·75, and at 16 he will probably have a mental age of 12.

> "The age at which intelligence reaches its maximum is the age at which there is no further growth of such abilities as those of memorising, of concentrating attention, learning or reasoning about new topics. It is certain that for the average individual this age is below 20. He may go on acquiring knowledge and wisdom all his life, but he works always with the same mental tools."

There is considerable variation, but probably on the average the maximum intelligence is reached at the age of 16.

A useful test is the Heilbronner test. This consists of a number of little cards in sets of three to seven, usually six. The first of each set shows the basic plan in the construction of some well-known object, such as a bicycle, a telephone, or a windmill; each succeeding card in a series shows a further stage in the setting up of the object, which, of course, it more closely resembles. The series is so arranged that any intelligent person can recognise each object, if not on the first card of the series, at any rate well before the final stage is reached. Cards for this test, like many other tests to be presently described, can be obtained from the C. H. Stoelting Company, 113, North Green-street, Chicago, U.S.A.

A Few Examples of Tests Devised by Healy.

Recently the recognition of the importance of individual examination and treatment in criminal work, as well as in educational, has done much to stimulate research. The outstanding investigator in this department is Dr. William Healy, who was formerly medical examiner in the Courts of Chicago, but has recently undertaken similar work in Washington. His book, "The Individual Delinquent," published in 1915 in London by Heinemann, is of outstanding importance. In this book many tests are described, of which the following are specially useful.

Picture form board.—This is a picture of a horse and colt in a field with some fowls. Eleven small pieces are cut out and can be removed from the board. "This test is to give interest and to get a first general measure of the individual." "At about 7 years of age any normal child should be able to do it in its entirety." "A young child will accomplish the task in a little over three minutes, while a bright child of 11 can often do it in less than two minutes."

Construction test "B."—This is a plain, rectangular piece of wood from which 11 pieces of varying size and shape can be removed. The test is to replace them correctly. Most normal offenders of 12 do this in from one to three minutes; the important point, however, in connexion with this test is the method of accomplishing it. What we want to see is "the attitude of planning as put over against taking the chances on trial and error, and particularly as against the repetition of impossibilities. This—namely, the ability to profit by experience—is registered with certainty in the number of moves made. Errors to the extent of 10 or 15 indicate little, but beyond that there is carelessness or actual inability to think out the situation. There are 11 pieces to put in; thus normally the task should be done in at least 26 moves. Occasionally a slap-dash method done by a bright person involves more moves, but only seldom. It should be remembered that a planful attack may be very slow." I have found this test helpful in forming an estimate of manual capacity. If a defective child does it rapidly and easily I always endeavour, if possible, to keep him outside an institution and let him try ordinary work.

Puzzle-box.—This is a square wooden box, the inside of which can be seen through a window in the lid. The lid is secured by a clasp fitting over an eye, through which is passed a staple kept taut by a ring attached to a cord, which passes into the box through a circular opening in the side. Inside the box this cord is kept taut by an arrangement of three other cords and rings passing over fixed metal supports, one cord passing through an opening in the side to be fixed elsewhere. A buttonhook is supplied, and by its use one of the rings can be slipped off its peg, and then by a series of moves the staple is freed and the box can be opened. "It is an example of a concrete problem to be reasoned out from perceived relationships; each step in the solution—namely, opening the box—is plainly visible." "Nearly all of our offenders above 12 who have ordinary ability can open this box well inside of ten minutes." The important point to observe is whether the correct steps are interspersed with errors; this should not be. This test is much more suitable for boys than girls. It is really a test of capacity for planning.

"*Aussage" or testimony test.*—This is a test of the ability to recall a scene that has been presented. The scene depicted is a butcher's shop, in which the butcher, standing with an upraised knife, is just going to cut off some of a string of sausages for a woman customer, who has a little girl and a dog with her. There are several other objects in the picture. "A bright child of 8 can give a good account of this, bringing out most points on cross-questioning, at at rate. A *good* account is 12 or 15 items on free recital, and eight or ten more on inquiry. A *bad* record is more than two or three errors, or acceptance of more than two suggestions."

Pictorial completion test.—This is a rectangular wooden board with pictures painted on it of several obvious situations, such as that of a boy who has just broken a window in a hut by throwing stones, while an old man standing by is pointing to the broken glass on the ground. The other incidents depicted include a little girl, whose hat has been blown off by the wind; a cart, the wheel of which has come off; a boy running away from a dog, and two boys playing with a football. Ten small squares, all of the same size, can be removed from the board. A number of alternative squares of the same size, and depicting either blanks or objects which would only appear to a person of low intelligence as suitable for filling in, are provided. The squares are removed from the board and then mixed with the alternative squares; the task is to replace the proper ones. In my experience this pictorial completion test sometimes gives important indications of moral failings and other poor capacities; but some moral imbeciles, especially those of the verbalistic type, come out well in this test, although they may fail badly with an apparently simpler one, such as the construction test "B."

Both the pictorial completion and the testimony test give some idea of the suggestibility of the person who is being examined. A more definite test of suggestibility is the line-copying test.

> "The subject is shown, one at a time, a series of lines printed on cards. The first three form a series of regularly increasing lengths; the remainder all have the same length as the third line. The subject is asked merely to reproduce the length of each line by drawing it on paper. The marked and regular increase in length of the first three serves as a suggestion that the increase will continue throughout the series, so that the subject may continue to increase the length of his copies long after the increase in length of the lines presented to him has stopped."

Moral Tests.

For this purpose Dr. Healy has a reaction test; this is in the form of the printed statement of two difficult situations, in each of which the question is what is the right course to take.

Dr. Guy G. Fernald, resident physician at the Massachusetts Reformatory, Concord, has also devised useful differentiating tests for the defective delinquent. He uses a series of 12 tests, which include some of those already described, and a set of ten questions, making up an "ethical perception test." There is also an ethical discrimination test, which consists of a list of ten offences, to be arranged in order of their gravity. The offences are:—

1. To take two or three apples from another man's orchard.
2. To take a cent from a blind man's cup.
3. To break windows for fun.
4. To throw hot water on a cat or in any other way cause it to suffer needlessly.
5. To break into a building to rob it.
6. To take money as "graft" or "rake off" when you are a city or Government official.
7. To try to kill yourself.
8. To get a nice girl into family way and then leave her.
9. To set fire to a house with people in it.
10. To shoot to kill a man who runs away when you try to rob him.

The ergograph affords an important test, not only for delinquents, but also for more ordinary defectives, especially when the question arises of their capacity for work in the ordinary world.

The Psycho-galvanic Reflex Test.

Reference may be made to the investigations of Dr. E. Prideaux in the Psychological Laboratory at Cambridge in regard to the psycho-galvanic reflex test. Dr. Prideaux says that:—

> "The factors which are responsible for the variation of polarising resistance in different persons is yet to be determined, but the evidence tends to show that the skin polarisation effects are correlated with the functions of the brain. So far as my experiments go at present, persons of the mentally deficient class tend to give a low psycho-galvanic reflex."

He also states:—

> "It is certainly my experience that the reactions in subjects of poor intellect, as evidenced by their low standard at school, are rarely so marked as in my intellectual subjects, and I have attributed this to the fact that the intellectual subject has usually a much greater control over his emotions, and has a wider range in the association of ideas."

The Need for a Series of Tests.

It is important to employ some series of tests in all examinations of defectives; in high-grade cases and criminals this is essential. When time is very limited, and a rough-and-ready estimate is all that is expected, I find that fairly definite indications can be obtained from the use of the following three tests: (1) The vocabulary test, as presented in the Terman Revision. This gives a rough indication of the mental age. (2) Healy's form board, which indicates the capacity for mental work. (3) Pictorial completion, which may give a clue to the moral character and type of mental make-up.

The mental examination in the American Army consisted first of the Binet-Simon tests or some modification of them, and, in addition, a large number of other ingenious tests which were divided into two sets according as to whether the recruit under examination was a "literate" or an "illiterate." The "literate" group, of course, were those who could read and understood the English language fairly well.[2]

It is interesting to note that American psychologists applied the army mental tests later to certain other groups. When used in *prisons* it was found that their use would lead to the segregation of the feeble-minded, but did not solve the problem of criminality. When *prostitutes* were examined it was discovered that 53 per cent. had a mental age under 10, and that 10 per cent. should have been in custodial institutions. A large percentage of those with a mental age over 10 had marked mental instability or actual mental disease. Only a small number were mentally normal. *Conscientious objectors* were found to have a mental age above the average. When applied to *industry* the conclusion reached was that the examination was very useful.

---

[2] Some of the American Army tests were shown, having been copied from "Mental Tests in the American Army," compiled and edited by Clarence S. Yoakum and Robert M. Yerkes, published by Sidgwick and Jackson, Ltd., London. Some of the Maze tests which have been found to be valuable were included in the American Army tests.

MENTAL AFTER-CARE ASSOCIATION.—A well-attended meeting of this association for poor persons convalescent or recovered from institutions for the insane was held at Bridewell Royal Hospital on Feb. 23rd by permission of the governors of that hospital. Sir Charles Wakefield presided, and made an eloquent appeal for further support. He alluded to the last year's accounts, which showed a deficit, and promised to give a donation which would wipe out the amount. After Dr. H. Rayner (chairman of the Association) had read the report, which showed the great increase in the work which has taken place during the last 12 months, Sir William Byrne moved its adoption, speaking in high terms of the way in which the association performed its duties and urging the great need for its ministrations amongst those patients who are discharged from mental hospitals. Amongst the other speakers were the Right Rev. the Lord Bishop of Barking, Dr. Hubert Bond, the Hon. John Mansfield (Lord Chancellor's Visitor in Lunacy), Mr. C. Gabain, Sir George Savage, and Mr. Ernest Sanger.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THEREPEUTICAL.

◆

A CASE OF

ENCEPHALITIS LETHARGICA COMPLICATING PREGNANCY.

BY J. BRIGHT BANISTER, M.D. CAMB., F.R.C.S. ENG.,
OBSTETRIC SURGEON TO QUEEN CHARLOTTE'S HOSPITAL, ETC.;
AND
G. SOPHIANOPOULOS, M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, QUEEN CHARLOTTE'S HOSPITAL.

NEVER having seen any reference to encephalitis lethargica occurring in pregnancy, we felt that a permanent record of the following case would be of interest.

The patient, a primigravida of 31, in the thirty-sixth week of pregnancy, was seen by one of us (J. B. B.) on Dec. 27th, 1920, in consultation with Dr. Pearson, of Hornsey, under whose care she had been for the previous nine days. She had been perfectly healthy up to Dec. 18th, when she went to her doctor complaining that she could not sleep, but had felt very heavy about the eyes for two days. On a routine examination being made nothing abnormal was discovered, and a sedative mixture was prescribed. Two days later (on the 20th) she complained of being unable to keep awake, of great pain when she raised her eyelids, and of slight tremors in the hands.

Other symptoms gradually developed, and when she was seen in consultation the general condition was as follows:—

A rather frail-looking woman in the thirty-sixth week of pregnancy. Complexion somewhat muddy and tongue furred. A very definite bilateral ptosis was noticed, and slight weakness of the right side of the face; pulse 110, temperature normal. She answered questions rationally; no definite twitching was noticed anywhere. Her relatives stated that the mental condition has varied from time to time. No headache or vomiting throughout the illness; knee-jerks exaggerated, that on the right being the brisker; apparently a slight loss of power in right arm and head.

A tentative diagnosis of encephalitis lethargica was made, and it was decided to transfer the patient to Queen Charlotte's Hospital for further investigation and treatment.

From her friends certain other points were elicited in addition to the changeable mental condition. They noticed very early in the disease a slight unsteadiness in gait which had become gradually more marked, while during sleep they had observed what they described as a "scrubbing" movement of the right hand. Her speech also had become less distinct and more halting day by day, while she had complained of "seeing double" on the third day of the illness. Constipation had been marked throughout.

On admission, the most apparent feature was a bilateral ptosis of a marked degree. There was an internal strabismus of the right eye. Horizontal and vertical nystagmus was elicited, the latter being very marked indeed. The pupils reacted to light and accommodation sluggishly and slightly; hippus was present; some irregularity in outline of the left pupil, but no anisocoria; discs normal. The face was mask-like, and the lower left quadrant appeared to be less mobile and more flattened than the opposite side; left angle of mouth was noticed to be twitching in a lateral direction. The tongue was protruded naturally, and was not tremulous; levator-palati contracted equally strongly; muscles of mastication and deglutition appeared unaffected; special senses not impaired, except the sight as already detailed.

Mentally the cerebration was slow; speech drawn and slurred, with an attempt at tailing off the sentences into a whisper; voice at no time normal in quantity, giving the impression of a lazy and effortless response. The intensity of the mental stimulus, although varied, could not influence the rapidity or the thoroughness of the reaction. Only at times was the patient noticed to be irrational in her replies.

The skin was dry and harsh, pulse rapid (110 on examination); katatonia could not be elicited. Reflexes all exaggerated; abdominal reflex not obtained, but because of the stretching of the parietes by the pregnant uterus much importance could not be attached to this fact.

The left upper limb (patient right-handed) appeared somewhat stronger than the right; no weakness detected otherwise. Triceps, pronator, and supinator jerks were obtained and were brisk. The right arm grips were all sustained and gave no impression of being lethargic in inclination. There was a peculiar pronatory movement of the right forearm, and the fingers were held in the position of writing. The rhythm appeared regular, but the frequency was not timed. The lower extremities appeared of equal and average strength; reflexes exaggerated, but clonus could not be elicited; plantar response slightly flexor; there was a marked protective reaction and the extensor fascia lata was noticed to contract. Sensation normal throughout; dermographism present to some extent. Rombergism not present, though the patient was very unsteady on attempting to provoke the sign. No ataxia. The patient had some hesitation in turning, comparable to the Parkinsonian manœuvre, and it was very apparent there was a definite list to the right side. False pointing to the outer side of an object was noticed. In certain respects the case was of the paralysis agitans type, showing some involvement of basal nuclei and red nucleus, mask-like expression, tremor (though this was not typical), increased reflexes, difficulty in turning, and the monotonous element in the speech. There was some indication of cerebellar involvement shown by the nystagmus, the false pointing, and the list in the gait.

The rapid pulse might be possibly construed as a removal of vagal control, though vagal function was not investigated. It was noted also that though the lungs were free from disease, respiration was rapid and noisy, though the accessory muscles were not brought into use. Lumbar puncture was performed on the fourteenth day of disease; anæsthesia with chloroform was employed for a lumbar puncture, without any untoward effect. The cerebro-spinal fluid was under pressure, and 30 c.cm. were withdrawn without completely relieving it; the fluid was clear and colourless, and bacteriogically sterile. The Wassermann, Nonne, and Lange tests were all negative. The cells were much increased, 348 per c.cm. being counted (48 per cent. polynuclear). The urine was free from albumin, casts, sugar, acetone, and diacetic.

Puncture was not repeated. The pregnancy was terminated by induction on the sixteenth day of disease. The child was perfectly healthy. A second anæsthetic had to be employed to end the second stage by the use of forceps. The pains were insidious and very effective, and the child was delivered nearly four hours after induction with two gum-elastic bougies.

The treatment besides this was the four-hourly use of 10 gr. of urotropine (which gave no rise to toxic symptoms) and the production of a fixation abscess in the thigh by the injection of 20 mm. of turpentine. The patient's mental state improved after delivery of the child on Jan. 2nd, 1921. The change, however, was short-lived: incontinence of urine and fæces commenced on the 5th, lethargy increased, tremors became more marked, pupils ceased to react to light, and deglutition became very difficult. The patient died on the 7th, three weeks from the onset of the disease.

Post-mortem was not obtained. The whole course was apyrexial except for slight rise to 100° F. a few days after the setting up of the *fixation* abscess.

The induction of labour was decided upon in view of the following facts: (*a*) The patient's condition was becoming continually worse; (*b*) the baby was alive; (*c*) it was hoped that the removal of the fœtus might influence the patient's metabolism for the better. The very definite improvement for the first 36 hours after delivery gave rise to great hopes of recovery, but the experience of this case leaves the question of interference with the pregnancy sub judice. It would be instructive to obtain speculations upon the advisability or otherwise of terminating pregnancy in cases such as the one under consideration.

A CASE OF
ACUTE DIVERTICULITIS.

By W. F. A. CLOWES, M.R.C.S., L.R.C.P. LOND.,

SURGEON, ESSEX COUNTY HOSPITAL.

THE following notes may be of interest, as they deal with a disease which I believe to occur more frequently than is generally supposed.

Mrs. P., aged 57, wife of a publican, was first seen for dyspnœa by my partner, Dr. E. F. Clowes, in March, 1919. She was a short stout woman, lived a rather sedentary life, and drank ale but no spirits; there were no apparent signs that she was an excessive drinker. She was not constipated and had no digestive symptoms. Dietary and treatment improved her so much that she was not seen again until Feb. 2nd, 1920, when she had an attack of diarrhœa and sickness, apparently caused by eating tinned salmon. A dose of castor oil and a bismuth mixture soon cleared this up and she did her usual work on Feb. 3rd. On Feb. 4th, whilst cleaning a fire-grate, she was suddenly seized with pain in the lower abdomen, so severe that she fainted. When seen at 3.48 P.M., about a quarter of an hour after the onset of pain, she was very collapsed, sweating, had a temperature of 97·4° F., and very small pulse, beating 146 per minute. She was vomiting at intervals of a few minutes a dark bilious fluid, and had hiccough. The abdomen was distended generally and did not move to respiration; it was rigid and very painful over the whole area below the umbilicus. The patient was removed as soon as possible to a nursing home. I saw her at 8.30 P.M. and decided to perform an operation; this was begun an hour later. She was then in such a collapsed condition that Dr. C. Sherris, the anæsthetist, considered a general anæsthetic inadvisable; the patient was extremely nervous of feeling any pain, so a whiff of ether was given, and a spinal anæsthetic administered. On opening the abdomen by a median incision I found a large quantity of purulent fluid with much recent peritonitis in lower part of cavity, especially the left iliac fossa. After mopping away the fluid I discovered the appendicæ epiploicæ were very much enlarged, being arranged on the convexity of the gut in two rows; they were of washleather colour, about the size of small grapes, and looked much like bunches of the latter. The large intestine from the rectum to the cæcum was affected in this way, but the sigmoid and lower part of descending colon was the part where the condition was most marked. The large bowel was very red, thickened, and rigid. A coil of small intestine was found attached by recent lymph to a small bunch of epiploicæ from the sigmoid, and here a leakage had evidently taken place. The condition of the large bowel and the great length affected made it impossible to do any kind of plastic operation, so the abdomen was washed out and drainage-tubes inserted.

Patient stood the operation well, considering her very collapsed condition, and on the following day was fairly comfortable but vomited frequently. This ceased on the second day, and she remained comfortable till the fourth day; diarrhœa and vomiting then set in again, continuing more or less until she died on March 3rd, 28 days after the operation.

Unfortunately, I was unable to obtain consent for a post-morten examination, which would have been most instructive. The appearance of the enormously enlarged epiploicæ and the way they were arranged when first seen at the operation gave the impression of malignant growth, and it was only on carefully examining it that its real condition was found out.

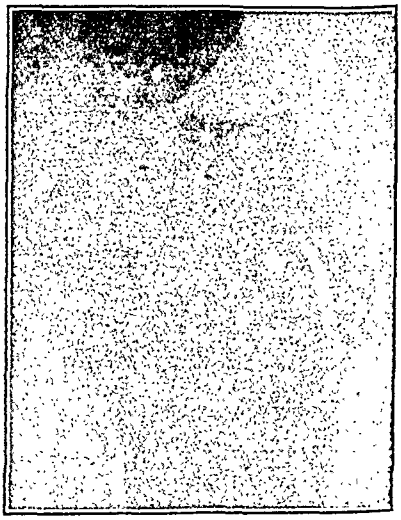
A NOTE ON
A CASE OF SCHLATTER'S DISEASE.

By ISAAC EBAN, M.A., B.SC. EDIN., M.B., B.CH.BELF.,

LATE CASUALTY OFFICER, ROYAL BERKSHIRE HOSPITAL, READING.

AN account of the following case is given here as it may prove of interest to casualty officers and out-patient surgeons at hospitals, besides recalling attention to a relatively rare condition.

A boy, A.W., aged 13, limped into the surgical extern of the Royal Berkshire Hospital one morning and complained of pain in the left knee of nine days' duration, idiopathic in origin. On examination the usual signs of inflammation were found in the region of the tibial tuberosity, and my first thoughts were of tuberculosis and of bursitis. The latter was soon ruled out, and as no other evidences of tuberculosis elsewhere were found, an X ray examination was made. An antero-posterior view of the knee appeared normal both on the screen and on the plate, but a lateral view revealed the typical appearance shown in the accompanying illustration. There is an irregular outgrowth of the tibial tuberosity somewhat resembling a forward displacement of the upper epiphysis, and this is quite characteristic. No history of injury could be obtained, although the boy played football for his school.



Radiogram of a case of Schlatter's disease.

Although the ætiology and pathology of the condition are still obscure, the treatment, which is therefore largely empirical, is usually quite satisfactory, comprising (1) rest, (2) back-splint, and (3) patience. The general consensus of surgical opinion is against operative treatment except in very marked or advanced cases. The most recent reference to this condition, as far as I know, occurs in the *Archives of Radiology and Electrotherapy* for May, 1920, where two somewhat similar figures are given.

The X ray plate was taken by Mr. A. L. Watson, radiographer to the hospital.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

CONGENITAL SYPHILIS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 25th, Dr. F. S. LANGMEAD, the President, being in the chair, when a discussion on Congenital Syphilis was opened by Sir HUMPHRY ROLLESTON, whose paper appears in full in the front part of this issue of THE LANCET.

Mr. O. L. ADDISON opened the

Discussion from the Surgical Side.

He said that the manifestations of congenital syphilis, which came within the province of the surgeon were, on the whole, less desolating than those with which physicians had to deal, for surgeons were spared the contemplation of the assaults made by the disease upon the central nervous system. Surgical lesions were so peculiarly amenable to treatment, if identified in time, that it was not necessary to labour the importance of early diagnosis.

The chief factor in successful diagnosis of most diseases was to be on the watch for them, for only so could one penetrate their manifold disguises, and it was a commonplace that syphilis was the most efficient masquerader of them all. Once suspected, the diagnosis in the forms of syphilis with which he had to deal could be decided by the results of treatment, with or without the help of the Wassermann reaction.

He described briefly the features of congenital syphilis. As far as rarities were concerned he would content himself with insisting again that one could not be too suspicious of lesions which, however variegated and anomalous, could conceivably be credited to a chronic inflammation.

At the present day we seldom saw the severer manifestations of the disease except in infancy; Hutchinson's triad—i.e., notched teeth, deafness, and interstitial keratitis—was uncommon, and it was much more usual for the lesion for which treatment was sought to be the only obvious sign of the disease. With the present system of antenatal treatment there was every hope that the syphilitic infant would soon be a rarity. There seemed to be no limit to the age up to which symptoms might continue to appear; at the present time he had a patient, aged 20, with old thickening of the *tibiæ*, who had just developed a gumma in the muscles of the leg, and interstitial keratitis. For descriptive purposes it was advisable to consider the manifestations of congenital syphilis in relation with two age-periods—viz., (1) infancy, and (2) after infancy.

(1) Congenital Syphilis in Infancy.

If we excepted "snuffles" there was only one common surgical lesion of congenital syphilis during infancy—viz., osteomyelitis of the long bones. It was seen most often at about 3 months of age, and started as a periostitis, rapidly becoming an osteomyelitis, and affecting as a rule the long bones of the arms and legs. The condition was generally more advanced in the arms than in the legs. X ray photographs were very characteristic. In the milder degrees they showed the periosteum raised from the shaft by a deposit of new bone. More advanced cases showed, in addition, large areas of absorption, most marked at the ends of the diaphysis.

Mild degrees of this osteomyelitis did not give rise to obvious symptoms, but he believed it to be an almost constant feature of infantile congenital syphilis, and he had frequently had X ray examination carried out in doubtfully syphilitic cases for the purpose of confirming the diagnosis. In advanced cases fractures were frequent. Owing to the absence of pain and swelling in the earlier stages, it was only the advanced cases which were recognised, and then under the entirely misleading name of "epiphysitis." The reason for this name was that changes were most advanced at the ends of the diaphysis, and consequently it was here that the tenderness and swelling were most marked. The child naturally refrained from use of any muscles attached to the inflamed periosteum, and a pseudo-paresis resulted. Later, effusion into the joint occurred, with or without a secondary infection, and separation of the epiphysis was not infrequent. He had not seen syphilitic arthritis in infants unassociated with osteomyelitis. Bending of the bone due to softening was said to occur, but he had seen no instances of this, though fractures were quite common and might cause deformity. There would be little or no difficulty about the diagnosis of these cases if X ray examination were made. He had met with no other disease which gave similar appearances in *all* the long bones.

Diagnosis had to be made from—

(1) *Periostitis and osteomyelitis of other origin*—e.g., staphylococcal, pneumococcal, tuberculous, &c. These were all extremely rare at the age when syphilitic osteomyelitis was most common—i.e., 3 to 4 months—and never did they affect all the long bones. The diagnosis was obvious from the X ray picture alone.

(2) *Scurvy.*—Here the age of the child, seldom under a year, and other obvious signs of scurvy were sufficient.

(3) *Poliomyelitis*, might be mistaken for the advanced stage of pseudo-paresis, but again an X ray examination of the long bones settled the question.

(4) *Acute infective arthritis*, which was most often pneumococcal, but might be due to almost any organism, even the *Bacillus coli* or the meningococcus. These might be differentiated readily from the syphilitic cases by X ray evidence of osteomyelitis in the latter, but it must be remembered that it was quite usual for a secondary infection to occur in the syphilitic cases.

(5) Cases of *renal insufficiency* associated with multiple fractures, such as were recently described before the section by Mr. D. H. Paterson, with X ray appearances not unlike late quiescent cases of syphilitic osteomyelitis, but the presence of *albumin in the urine* and a *negative* Wassermann reaction would indicate the correct diagnosis.

Dactylitis was extremely rare; he had only seen one or two instances.

Orchitis was the next infant lesion in order of frequency. It was common at birth or in the first month or so, and appeared as a hard, painless enlargement, usually symmetrical and accompanied by a small hydrocele. A few cases of broken-down gummata of the testicle had been recorded, the earliest at the age of 9 weeks. He knew of no other lesion for which this could be mistaken. Tubercle of the testis occurred at a later age.

(2) Congenital Syphilis after Infancy.

In this period bone and joint affections were still the most frequent manifestations. There were two forms of bone involvement, periostitis and osteomyelitis.

Periostitis occurred at the age of 3 to 4 years or later and was either diffuse or localised, the diffuse form giving rise to the well-known sabre tibia, the localised form to nodes; both were commonest on the tibia, but might occur on other long bones, and the node not uncommonly on the cranial bones and vertebræ. The diffuse form rarely broke down, whereas the node commonly did. Both forms led to the formation of a large quantity of sclerosed bone, except in the cranium and vertebræ.

General osteomyelitis affecting a part or the whole length of one or more long bones was much less common. It gave rise to an enormous general increase in amount and density of the compact bone, with areas of softening and formation of sequestra in the medulla. Lesser sinuses formed and the condition was clinically indistinguishable from a chronic osteomyelitis of staphylococcic or other origin. Overgrowth in length and bending might occur, or shortening if the epiphyseal cartilage was involved.

With regard to diagnosis, in diffuse periostitis the perfectly smooth even deposit of new dense periosteal bone was unlike any other condition which he knew of. There was no excuse for mistaking the rickety tibia for syphilitic periostitis.

Local periostitis in long bones might occur anywhere in the length of a long bone, but usually was near one or other end of the diaphysis. A green-stick fracture without bending or a simple traumatic periostitis might be mistaken clinically for an early stage. In more advanced cases there was often a very great enlargement of the bone, and a diagnosis of sarcoma was frequently made on clinical grounds, but an X ray examination showing the often enormous formation of dense bone would settle the question. From an enlargement due to tuberculous abscess or osteomyelitis an X ray test was conclusive, for in tubercle rarefaction and absorption with very little new formation or sclerosis of bone was usual. Many of these syphilitic cases had been described as a hypertrophic form of tuberculosis of bone. Localised periostitis of the cranial bones was frequent and often indistinguishable clinically from sarcoma or tubercle, though the latter was extremely rare.

From the local forms of osteomyelitis, tubercle and sarcoma might be indistinguishable clinically, but here again an X ray examination was conclusive, but it might not be so from a chronic abscess of bone due to staphylococcus.

In diffuse syphilitic osteomyelitis the onset was never so acute as in the more common forms due to staphylococci, &c., but a certain diagnosis could seldom be made on clinical or X ray evidence, and reliance must be placed on the presence of other signs of syphilis, the Wassermann reaction and the results of treatment.

Joint lesions were of three types; two of these were common—gummatous synovitis and symmetrical serous effusion, and one was very rare—chondro-arthritis.

Gummatous synovitis was seldom recognised as it was indistinguishable clinically from tubercle; in both muscular spasm and wasting were present, and it was commonly unassociated with other signs of congenital syphilis. Another point of resemblance to tubercle was that the joint might recover with simple splinting. These cases differed from tuberculous joints in that there might be considerable overgrowth, and that shortly after the removal of the splints there was perfect recovery of movement. In gummatous synovitis X rays frequently showed a layer of new periosteal bone at the end of the adjacent bones. This condition was usually monarticular, and might affect any of the larger joints.

Symmetrical serous effusion (Clutton's joints) most commonly affected the knee-joints. The condition was usually much more marked in one of the joints, the other frequently escaping the parents' notice. There were considerable effusion and a variable amount of synovial thickening. The symptoms were slight, little or no pain being felt except after prolonged use. Muscular spasm was absent, wasting slight, and the movements were free except for mechanical limitations.

Chondro-arthritis was rare, and one of the later manifestations; it was characterised by effusion, by thinning and ulceration of cartilage, and erosion of the underlying bone. The synovial membrane was thickened and fringed. Several joints were affected. G. F. Still described another type with much limitation of movement and no effusion, closely resembling a rheumatoid arthritis.

Other rarer lesions of congenital syphilis belonging to this age were:—

(1) *Gummata* in muscles, often reaching a large size. Gummata of the skin and subcutaneous tissues, unassociated with underlying disease of bone, were very rare, but cases with extreme extensive destruction of the lips and nose had been recorded. He had seen one case of multiple gummatous ulceration of the skin and one or two of rupia. As a rule the so-called cutaneous gumma was a tuberculide. The diagnosis of gummata in muscles from any chronic inflammatory mass might be impossible clinically, and recourse must be had to the Wassermann reaction, and, if necessary, exploratory operation and bacteriology or a microscopic examination. Sarcomata might generally be diagnosed by their better definition, though a diagnosis might be impossible without an exploratory operation.

(2) *Ulceration* of the hard or soft palate and glossitis were not uncommon.

(3) *Chronic enlargement of the glands of the neck*, often forming a mass of considerable size and indistinguishable clinically from enlarged glands due to tubercle or any other chronic inflammation, was fairly frequent.

Diagnosis and Treatment.

Diagnosis in the presence of the commonly accepted signs of congenital syphilis—viz., depressed nose, Hutchinson's teeth, interstitial keratitis, &c.—was simple, and the diagnosis of any given lesion had only to be suspected to be immediately confirmed.

Unfortunately, many of these cases showed no clinical signs other than the lesion for which treatment was sought, and these lesions so exactly imitated those of other and more common diseases that the correct diagnosis was not thought of. The most striking example of this mistake, in his experience, was gummatous arthritis; in these cases other clinical signs of syphilis were usually wanting and a diagnosis of tubercle was almost invariable. Unless a Wassermann reaction was done as a routine in all cases of suspected tubercle of joints and spines the majority of these cases would be missed. Congenital syphilis could, and did, imitate exactly nearly all the lesions of tubercle, and he thought that this was responsible for the statements seen in the older text-books that the association of the two diseases was very common. He had only had one case where he was able to prove the presence of both syphilis and tubercle. In doubtful cases diagnosis could only be made on the Wassermann reaction and the results of treatment.

He would leave a detailed consideration of this to Dr. Nabarro, who had given the general treatment in a large number of his cases.

Constitutional treatment, he considered, was all-important and he believed strongly in a course or courses of intravenous or intramuscular injections of novarsenobillon with prolonged use of mercury; of the two drugs, he believed mercury to be of far greater value, but courses of the drug must be given over a period of many years. He preferred to use it in the form of equal parts of ung. hydrarg. and lanoline. With this he used to get excellent results before the days of arsenobillon. He had not yet known of a child with a Wassermann reaction originally positive becoming negative as a result of treatment and remaining so permanently. It was possible, and he thought likely, that in some cases the virus did die out, but seeing that latent periods with entire absence of symptoms might last for 30 to 40 years, we could not say that a patient was cured even if the Wassermann reaction remained negative for 9 or 10 years.

Juvenile General Paralysis.

Sir **FREDERICK MOTT** described cases of infantilism, and showed lantern slides of juvenile general paralysis.

He remarked that among 40 cases of this disease resulting from congenital syphilis only about one half showed obvious clinical signs, but the history of miscarriages, abortions, and children dying in early infancy was followed by this form of late syphilis of the nervous system. He stated that he had examined the testes in a number of cases of juvenile general paralysis and he had observed that those with infantilism exhibited arrest of development of the spermatic tubules so that they presented the same appearances as the sections of the testes of a newborn infant. The interstitial cells of Leydig were not visible and there was replacement by a lymphocyte infiltration. In cases which presented no clinical evidence of infantilism, the seminal fluid contained normal spermatozoa; in one case living spermatozoa were found in the fluid eight hours after death. These testes also showed the interstitial cells of Leydig. Although he had found spirochætes in an emulsion of the brain in ·66 of 100 successive cases of G.P. he had not once found in 50 cases spirochætes in an emulsion of the testes. He had examined the pituitary body in a few cases of general paralysis and tabes, but he had never seen spirochætes or any evidence of syphilitic inflammation. He was of opinion that affection of the endocrine organs would be associated in the great majority of cases with a general spirochætal septicæmia that would terminate fatally in early infancy. He finally referred to facts pointing to the probability that the spirochæte causing tabes and general paralysis was an attenuated form—possibly, as Levaditi and Marie suggested, neuropathic, as distinct from dermatropic. The history of the majority of the cases of juvenile general paralysis did not support this hypothesis of a distinct organism.

Treatment in Relation to the Wassermann Test.

Dr. **DAVID NABARRO** said that his experiences referred almost entirely to the V.D. clinic at the Children's Hospital, Great Ormond-street. Compared with those of some observers, his record of cases might not be a large one, but he was in the fortunate, and possibly unique, position of taking the bloods and doing the Wassermann tests, and of treating and watching the cases himself. Thus, during the year 1920 he saw 68 new positive cases, did 662 Wassermann reactions, and treated 77 patients with 530 injections.

Until the end of last year he used novarsenobillon for the injections and with no ill-effects except a little sickness in a very few cases. He was now using neokharsivan for some patients and found that it increased the number of cases of vomiting immediately after the injection. Intravenous injections into an arm or the external jugular vein, but never into the superior longitudinal sinus, were given whenever possible. In the absence of a suitable vein the injections were given intramuscularly, and the drug was used in simple watery solution for both kinds of injection. For infants under 1 year the initial dose was 0·05 g., increasing to 0·1 or 0·15 g. For larger children the initial dose, according to the size of the child, was 0·1 or 0·15 g., increasing to 0·3 or 0·45 g. A course consisted of six weekly injections of N.A.B. and simultaneous inunction with mercury ointment. At the end of the course some potassium iodide or syr. ferri iodidi was given for three weeks and then a Wassermann test taken. If necessary the course was repeated once or twice or even more often. Several of his patients had had 18 to 24 injections totalling from 5 to 7 or 8 g. of N.A.B., and one boy had had over 10 g. of galyl and N.A.B. in 28 injections without any ill-effects and, it should be added, with no effect upon the very strongly positive Wassermann reaction of his blood.

With regard to the Wassermann test, he had great faith in this when *reliably* done, and believed that a "strong positive" always means syphilis. One must remember, however, that a positive Wassermann did not always prove that a particular lesion in a child was syphilitic in nature. Thus he had seen a tuberculous bone lesion in a syphilitic child and quite recently a case of poliomyelitis. A negative Wassermann did not always preclude syphilis. Very young children might give a negative reaction, so that he invariably tested, whenever possible, *the blood of the mothers of infants under a year.* The mother's blood was practically always positive (but varied in degree) when the child's blood was positive. Very rarely was the mother's blood negative when the child's was positive. He had found that the father's blood was frequently negative. Other children in the family might have a strongly positive Wassermann reaction. He was treating some of these cases, even in the absence of any symptoms, in the hope that thereby the later manifestations of congenital syphilis—especially the serious eye and ear lesions—might be averted.

As a result of the combined treatment with arsenic and mercury many of the patients were much benefited, but it was as yet too early to say that they were cured. Hearing might improve, ulcerations of the palate heal quickly, hæmoglobinuria be prevented, even mentally defective patients become brighter and less noisy and troublesome to their parents, as well as more intelligent. The keratitis cleared up more thoroughly perhaps than with mercury alone, but *he could not say if the duration were shortened.* Many of the young patients developing a rash at four, five, or six weeks died in spite of the treatment.

In congenital syphilis, so far as his experience went, the Wassermann reaction could not easily be made negative. As already mentioned, one patient had had over 10 gr. of arsenic compound and much mercury, and his blood was still very strongly positive. Out of 62 treated cases the Wassermann reaction had at some time or another become negative in only 14, and in five of these cases it had since become positive again.

Lastly, in view of: (1) the difficulty of certainly curing cases of congenital syphilis; (2) the heavy infantile mortality for which syphilis was directly and indirectly responsible; and (3) the large amount of mental and physical disability which congenital syphilis produced—especially mental deficiency, impairment and even total loss of sight and deafness—it was obvious that attempts should be made to treat the child before it was born by treating the mother. It had *now been abundantly proved that by treating a prospective* mother by the combined method she would be delivered of a healthy child, in most cases.

Obstetric and Antenatal Standpoint.

Dr. **AMAND ROUTH** said that he wished to speak from the obstetric and antenatal standpoints, for congenital syphilis could never be stamped out unless the infected fœtuses were treated through their mother during pregnancy. Probably the deaths of the embryos and fœtuses were as numerous during their mother's pregnancies as the deaths of the surviving infants during the first year of life, which latter, in 1919, amounted to 61,715. It had been estimated that in each of these periods about 16 per cent. of the deaths were of syphilitic origin, which would mean that 20,000 potential citizens died annually between fertilisation of the ovum and the end of the infantile year. Many of the intra-uterine deaths would occur very early in pregnancy, before nature's protection or treatment of the mother could effectively operate, and the abortions would be unrecognised as such.

The infantile deaths of syphilitic children would occur chiefly at two periods, the one during the first week or two after birth, due to the debilitated newborn children being unable to stand the strain of birth, the other later on in the infantile year when congenital syphilitics, born apparently healthy, had become clinically syphilitic. The tendency for weakened children to die soon after birth was shown by the fact that in 1919, out of 61,715 infantile births 8383 died in the first 24 hours of life, and 9388 in the first six days, together being more than a fourth of the infantile deaths. The reduction of infantile mortality in 1917-18-19 had been entirely from reduction of causes operating in the later months of the infantile year.

Owing to the absence of a scheme of confidential death certificates *in this* country *(alone in this respect amongst* European countries) the mortality of congenital syphilitic children who had not been treated through their mothers during pregnancy was not known; but Dr. Helen Campbell, head of the Infants Health Department in Bradford, reported that in 1918, out of 1606 children under her care, 148 died, and of them 120 (81·08 per cent.) were congenital syphilitics. Of the 107 legitimate children who died, 83 (77·5 per cent.) had congenital syphilis, and of the 41 illegitimate children who died 37 (90·2 per cent.) had syphilis. Dr. Helen Campbell said that these deaths of congenital syphilitics were due to the fact that they were peculiarly selected for attack by respiratory and gastro-intestinal and specific (measles) infections which killed them in much larger numbers than infants not so affected. Obviously these children, infected from their conception, must be treated during their mother's pregnancy if they were to be born healthy. Up to 1905 pregnant mothers *who had previously had syphilitic children were treated by* mercury from the third month of pregnancy, and healthy children were born and reared, but the treatment had to be adopted at each subsequent pregnancy. Was this necessary now under salvarsan treatment? There was no doubt, however, that treatment should be begun as early as possible, though Mr. John Adams, Mr. Charles Gibbs, Dr. J. H. Sequeira, and Dr. Morna Rawlins had proved that treatment of the pregnant mother by salvarsan could be begun as late as the seventh or eighth month, with the great probability that a healthy child would be born. This was a surprising result. Such a cure could not happen in cases where the child's organs were already diseased and full of active spirochætes, but only where the infection was in a quiescent stage rendered latent by natural agents.

Latent Syphilis in Pregnancy.

The fact of latent syphilis in pregnancy was now admitted to be frequently present, especially as regards the child. If this were not so, no infected fœtus could live in utero for nine months with active syphilis progressing. The ovum could be infected at fertilisation or soon after, whilst implanted in the uterine mucosa, by early granule stages of the mature spirochætal organism. These granules were the result of the spontaneous breaking up of the spirochætes. Noguchi had described how he had reared such granules in a series of cultures from 1910 to 1917 and had seen them "sprout" and develop into the mature spirochæte capable of infecting monkeys and rabbits. Sir F. W. Mott had quoted O'Farrell and A. Balfour to show that injection of salvarsan caused shedding of granules from the *Spirochæta pallida*, and he himself believed that a similar result was obtained by the action of the syncytial toxins formed throughout pregnancy, during the trophoblastic action of the cells of the chorionic villi, whilst burrowing into the maternal tissues at the placental site, at the point of union of the mother and fœtus. The infection was, he believed, rendered latent by the granules being kept biologically inactive, perhaps by the prompt destruction of their delicate reproductive "sprouts." In such cases the child would be infected by the inhibited granules and have a negative Wassermann, and if the mature organism were absent also from the mother's tissues she also might be negative during the pregnancy. If the mother had not been treated during her pregnancy the child might be born apparently healthy owing to the infection being latent, but as the syncytial toxins (or "chorionic ferments") disappeared from its tissues, the granules would begin to develop into the mature organism and the child would give a positive Wassermann reaction, owing to enough antibodies being produced to excite a general reaction in its blood; the child would then become clinically syphilitic. Occasionally, the natural protection afforded by this syncytial action would be so strong that the granules would not only be inhibited but destroyed, and the child would be born free of syphilis. This explained the occasional birth of a healthy child amidst a series of stillbirths or infected children.

The cause of death was "unknown" in about 25 per cent. of stillbirths, and in a larger proportion of abortions. Dr. Eardley Holland was working at this problem and considered that in the absence of spirochætes, chondro-epiphysitis was a certain sign of syphilis, whilst enlargement of the liver and spleen were less certain indications. He thought that further research would reduce the large class of "unknown" cause of death in macerated fœtuses and increase the class of cases due to syphilis. It might also be possible, by staining or culture, to recognise earlier stages of the mature organism. With our present knowledge congenital syphilis could be prevented or cured if every syphilitic mother were treated, not only during her pregnancy but in anticipation of the next pregnancy, till she was definitely cured. The child might, however, need treatment after birth for a length of time not yet agreed upon. There must be serious cases of embryonic fœtal infection where it was not rendered latent early enough *to save the child's life, but all such cases* would terminate in abortion or stillbirths. All other cases seemed to be amenable to modern treatment during pregnancy up to the seventh or eighth month.

The real difficulties were, he said, (1) to get the mothers under medical supervision for diagnosis and treatment; and (2) to be able to enforce treatment for a sufficiently long time to get the desired result. If these difficulties could be surmounted congenital syphilis could be stamped out by antenatal treatment of the mother.

Blindness and its Associated Symptoms.

Mr. **BISHOP HARMAN** described the associated symptoms found in 600 cases of children blinded from the effects of congenital syphilis. He stated that the cases were the collection of 17 years, and that they had been under his care for an average time of six years, so that there was ample opportunity for observation.

Dividing the cases into two groups as to whether the front or back parts of the eyes showed the most manifest inflammatory effects, he found 398 cases of interstitial keratitis and 229 cases of disseminated choroiditis. Amongst the group of interstitial keratitis the main associated symptoms were: Hutchinson's teeth, 265; physiognomy, 115; iritis, 128; bad family history, 170; scarred mouth, 61; bone or joint disease, 26; ulceration of nose or palate, 15; deafness, 63. Amongst the group of disseminated choroiditis numbering 229 there was optic atrophy in 117; Hutchinson's teeth, 97; physiognomy, 53; bad family history, 115; bone or joint disease, 19. deafness, 51. Comparing the frequency of the chief associated symptoms of the two groups, it was found that the characteristic teeth were present in 73 per cent. of keratitis and 46 per cent. of choroiditis, bad family history in 47 per cent. of keratitis and 55 per cent. of choroiditis, gross mental disorder in none of the keratitis cases but in 41 per cent. of choroiditis. Bad family history was shown by the high rate of miscarriage, stillbirth, infant death, and diseased children. Amongst 150 syphilitic mothers there were 1000 pregnancies, with only 390 presumed healthy children. Amongst 150 average hospital mothers there were 826 pregnancies, with 654 healthy children, or 792 per 1000, so that the average mothers produced twice as many presumed healthy children as the syphilitics.

The discussion will be reopened on Wednesday, March 16th, at 8.30 P.M., by Dr. Morley Fletcher, and continued by Mr. John Adams and others.

COMBINED MEETING OF CLINICAL, MEDICAL, AND SURGICAL SECTIONS.

GRAVES'S DISEASE: ITS MEDICAL AND SURGICAL TREATMENT.

THE adjourned discussion on this subject was continued on Feb. 25th, Sir ANTHONY BOWLBY, President of the Clinical Section, being in the chair. A report of the opening of the discussion appeared in THE LANCET of Feb. 19th (p. 379).

Surgical Treatment of Hyperthyroidism.

Mr. **DONALD ARMOUR**, in reopening the discussion, said that it was regrettable that a name based on its pathology had not yet been adopted generally for the symptom-complex. "Exophthalmic goitre," descriptive of two of its most obvious symptoms, was often a misnomer from the absence of one or other or both of them. Moreover, the addition of the qualifying terms "true" and "false" would only add to the confusion. He would urge that the term "hyperthyroidism" should more generally be applied to this disease as being a more accurate and scientific description. His experience of the surgical treatment extended over some 15 years and included about 200 cases. Surgical treatment was based on the view that this disease was primarily one of the thyroid gland, and that the resulting symptoms were due to a disturbed function of that gland "probably to hypersecretion of materials which induce a sort of chronic intoxication" (Osler). Surgical treatment was directed to lessening the overaction of the gland or diminishing the amount of its perverted secretion, either by reducing its blood-supply by ligation of arteries or by ablation of more or less of the gland substance. These results were more certainly and more permanently attained by surgical treatment than by other means. With greater experience in operative and anæsthetic technique and increased knowledge of the disease the surgical risks had been greatly reduced in the last few years.

The general anæsthetic bogey, he hoped, had been laid finally to rest. A technique evolved by a skilled anæsthetist from long experience of these cases, one with whom he had worked in frequent association, had relieved him from all anxiety with regard to the anæsthetic, which in his practice was always a general one. In those cases in which, from the condition of the patient, it was thought advisable to "steal the gland," as Crile called it, the method carried out by his colleague, Mr. H. M. Page, was briefly as follows. The preliminary treatment was described to the patient as consisting of hypodermic injections and rectal enemata. For several days preceding the operation hypodermic injections of distilled sterile water were given, followed by small saline injections per rectum. The saline was changed to olive oil for a day or two, and finally on the day fixed for the operation—of which the patient had no knowledge—a hypodermic of morphine and atropine was given, followed by ether and olive oil by the rectum. He had found rectal ether an ideal anæsthetic for these cases. Chloroform as an anæsthetic should never even be mentioned.

The anæsthetic bogey looked like being replaced by another, that of damage to the recurrent laryngeal nerve. Unquestionably injury to this nerve might take place, and was a very serious operative result, but it could be avoided by skill and experience. A specimen had recently been shown in which the recurrent laryngeal nerve before going into the larynx broke up "into a leash or plexus." The opinion was expressed that "that was probably invariable, and it was almost impossible to enucleate the lateral lobe of the thyroid without damaging one of these branches." On this question he had consulted Professor Arthur Keith, who had told him that he had knowledge of such behaviour from the work of Mr. F. G. Parsons, but that it was "probably invariable" he did not agree. Nor did a search of the specimens in the Hunterian Museum reveal a single example of such behaviour. Nor did Professor Keith agree with the second deduction, because the nerve neither entered the gland nor pierced the capsule, and could easily be avoided with reasonable care during the operation. The requisites, in addition to a knowledge of the anatomy, were the use of the greatest gentleness and deliberation in that part of the operation which had to do with the gland itself. He thought that the risk was still further reduced by following Charles Mayo's suggestion of wiping down the capsule off the gland with gauze. Moreover, the inferior thyroid vessels should be secured within the capsule as near the gland substance as possible. "Considerable traction on the gland and free use of the scissors," as described by one writer, would certainly, sooner or later, result in injury to this important structure.

With regard to the amount to be removed, he had always acted empirically and removed one lobe, the larger if they differed in size, together with the isthmus. Other surgeons did likewise, and advised further subsequent removal if indications arose. Might not this method result in the removal of too much gland at the first operation? It was so in the case he had shown. A hemithyroidectomy had been done with excellent results as far as the hyperthyroidism was concerned, but the patient had now gradually developed symptoms of hypothyroidism, controlled only by thyroid extract. Would it not have been sufficient to have tied the superior thyroid arteries? Ligature of the arteries had a definite place, either as a preliminary to future gland removal, or as the only operation necessary. He had been struck by the excellent results obtained by ligature alone in a few cases. These two operations alone should have a place in the surgical treatment of the disease.

Every case at any period of its course was not suitable for surgical treatment, nor should surgical operation be blindly applied to every case. The surgical treatment of hyperthyroidism was *not* an emergency operation, and cases should come to operation only after such treatment by rest and medication had been undergone as was necessary to make them suitable for operation. The symptoms contra-indicating immediate operation were progressive and rapid emaciation, acute cardiac dilatation and myocardial exhaustion, persistent vomiting and diarrhœa, and marked mental symptoms. In general terms acute cases were also unsuitable for operation immediately. On the other hand, the cases called by Kocher "secondary Graves's disease" were particularly suitable for surgical treatment.

Treatment by X Rays.

Dr. **FLORENCE STONEY** gave particulars of 200 cases showing the benefit accruing from treatment by X rays; 185 were of women and 15 of men.

Graves's disease, she said, was essentially a disease for the physician. Two lines of treatment were indicated, one to lessen the activity of the thyroid, the other to remove the cause, the bacterial toxins responsible. The radiologist or surgeon was necessary in every case to complete the former. X rays acted as a specific; they brought about partial atrophy of the thyroid gland, which could be stopped at any time it was thought desirable. In the early cases the action was rapid, but in chronic cases, and in later stages much patience was required to get satisfactory results. X rays attained the same aim as the surgeon without danger or pain. The three disadvantages were the delay in obtaining results, telangiectases at the site of the application, and scarring of the neck by prolonged treatment in chronic cases. An essential to the treatment was removal of the primary cause and control of the source of toxæmia, whether oral sepsis, otorrhœa, chronic appendicitis, intestinal stasis, or other source. Additional measures of value were mental quietude and endocrine therapy.

It was not advisable to wait for exophthalmos or goitre before making the diagnosis or commencing treatment, and considerable reliance in early stages could be placed upon the rapid pulse and toneless first sound. The disease required treatment from the dentist, physician, and radiologist working in combination.

Results of Treatment at Guy's Hospital.

Dr. J. M. H. CAMPBELL had investigated the results of the cases of Graves's disease treated at Guy's Hospital from 1908–17 with a view to comparing the figures with those of Sir William Hale-White of an earlier series, and to estimating the prognosis.

There were 127 cases, of which 8 terminated fatally in hospital, either directly from Graves's disease or from terminal infections; 1 patient had died from carcinoma of the pancreas. Eighty of those discharged from hospital had been traced for periods of from 4 to 12 years; of these 7 died from exophthalmic goitre and 5 from other diseases. These 80 cases, together with the 8 who had died in hospital, were arranged for statistical purposes into five groups. Group I., cured completely 7, or 8 per cent.; Group II., almost cured with but few signs remaining 26, or 30 per cent.; Group III., much improved and able to do light work 29, or 34 per cent.; Group IV., little or no improvement 11, or 13 per cent.; Group V., died (8 in hospital, 7 afterwards) 15, or 15 per cent.

The percentages were calculated on the total number of 127 cases, making use of the assumption that among the 38 not traced the relative results were the same as among the 80 who could be traced. In arriving at a comparison between surgical and medical treatment 5 cases treated surgically were excluded, as they died within a year and therefore came among cases which many surgeons would have considered inoperable. There had been no deaths from the operation itself. The cases which formed the basis for these figures were 16 treated surgically and 56 treated medically. The figures for the corresponding groups were as follows: Groups I. and II. (cured and almost cured), surgical 38 per cent., medical 41 per cent.; Group III. (much improved), surgical 38 per cent., medical 28 per cent.; Group IV. (not improved), surgical 12 per cent., medical 17 per cent.; Group V. (died), surgical 12 per cent., medical 14 per cent. He suggested that the reason why a second operation might become necessary was, perhaps, that after the first operation the gland responded again to the stimulus, whether psychogenetic or toxic, which had provoked its original enlargement. The results were too few for definite conclusions, but showed that partial thyroidectomy was not always so preferable that one ought to forget the possible danger of operation and advise it on every occasion.

Selection of Cases for Operation.

Mr. W. H. C. ROMANIS considered especially three aspects of the question: (1) the selection of cases for operation; (2) the nature of the operation to be done; and (3) the after-results of operative treatment. It was not unusual, he said, to find that some observers labelled many cases "Graves's disease" when the symptoms and physical signs were not sufficiently pronounced to merit that name. Nor was it unusual to find patients with adenoma of the thyroid, parenchymatous goitres, and even malignant thyroids, exhibiting palpitation, nervousness, rapid pulse, and tremor; but he did not regard these as Graves's disease, and thought that the name should be applied only to those patients who in addition had a noticeable change in the eyes, and definite cardiac enlargement.

1. As regarded the decision whether such a case was likely to benefit by operation, we must consider whether mild cases should not have medical treatment first; if all signs and symptoms were slight, not progressing, and of short duration, medical treatment would often give benefit, though frequently only temporary. But in moderately severe cases or in patients in whom any one sign or symptom was present to a marked degree and progressing, medical treatment was only of value as a preliminary to operation, and should only be indulged in for two or three months. Unfortunately, many patients were not advised to have surgical treatment until the condition was so severe that risk of operation had to be balanced against the benefits which might follow it, though in dealing with so serious a disease a small risk was justifiable in an attempt to obtain a cure. He did not regard great rapidity of pulse-rate, irregularity, marked cardiac dilatation or fibrillation, acetonuria, diarrhœa and vomiting, serious loss of weight as any contra-indication to operation, provided that the patient was anxious to have operation done and that her mental condition was moderately good. Marked nervous excitability (almost always present) was no bar to operation, but melancholic, delusional, or maniacal symptoms forbade operation, for it would lead to no improvement. Age of over 60, diabetes, great fear or unwillingness to have operation, or œdema due to a failing heart, contra-indicated surgical treatment. Patients who submitted to operation unwillingly did not benefit from it as much as those who were anxious to have it done; but most of the hypersensitive, nervous patients willingly underwent operation.

2. The nature of operation to be done. Removal of a large portion of the thyroid gland was the procedure of choice. Whatever the cause of the enlargement might be (infection possibly) the enlarged gland was the factory of the symptoms, and by reducing its activity we could cure them. Hemithyroidectomy was never sufficient; one lobe, the isthmus, and at least a quarter of the other lobe, was the minimum amount to be excised. Hemithyroidectomy would produce an improvement, but not a cure. It was most important not to leave behind small portions of the lobe which was being removed, on the recurrent laryngeal nerve or on the superior thyroid artery, as was done by some surgeons, and also that the tongue-shaped process which often passed behind the larynx should also be removed, for otherwise the pieces left behind hypertrophied and caused persistence of symptoms and subsequent relapse. Milder cases could safely be operated on under open ether or rectal ether, but severe cases were subjected to a much smaller risk if done under local anæsthesia; anxiety and fright would not in this case be present if morphia and hyoscine were first given; if this was done 90 per cent. of the patients declared afterwards that they had no recollection of the operation at all, even though they might have cried or talked during it. Many patients asked to have it done under local anæsthesia. In very severe cases a second or even a third operation might be necessary.

3. The after-results. In the very severe cases the patients seemed to obtain even greater relative benefit and were more pleased with their improvement after operation than were those more slightly affected. As regards mortality, out of about 220 thyroidectomies done for this condition, mostly under local anæsthesia, five had died (two of pneumonia) a mortality of just over 2¼ per cent. Many of these patients had pulse-rates of over 170. Usually after thyroidectomy there appeared to be more improvement in the subjective symptoms than in the physical signs. Patients looked better and felt much better within a day or two, but the physical signs might take some weeks to improve. As a rule, four months after an adequate thyroidectomy patients felt well, slept well, ate well, and could do their day's work and put on weight, but the pulse-rate, though much slower, was not quite normal; the cardiac dilatation was very much less. Irregularity of pulse, diarrhœa and vomiting, and acetonuria invariably disappeared, but the eyes, though much less prominent than before, rarely returned completely to the normal. It might be thought that if even more thyroid tissue had been removed these physical signs would be improved still further, but he doubted it. For though a second operation was often worth while if the subjective symptoms had not quite gone, it did not produce much further improvement in the eyes and pulse-rate, whilst in the few total thyroidectomies he had done for Graves's disease the physical signs had never quite completely disappeared. He would like to receive information on the following points: Were not the parathyroids a physiological myth, and did they really exist as functioning organs? After complete removal of the whole thyroid gland for malignant disease or for Graves's disease, and after the second and third operations for removal of thyroid tissue, all done without paying the slightest attention to the parathyroids, he had never seen any symptoms of parathyroid insufficiency, and he knew no surgeon who had. In fact, tetany seemed to be more common after gastric operations than after thyroid operations, and he was tempted to doubt whether in man the parathyroids played so important a part as the physiologists would have us believe.

Surgical Treatment of Medical Failures.

Mr. A. J. WALTON said that his experience of exophthalmic goitre was based upon 101 cases which were in a sense selected cases, since all had had medical treatment which had failed to cure them. If operative treatment was to be accepted as a routine measure two premisses must be granted: (1) that the disease was due to hypersecretion; (2) that the results of medical treatment were unsatisfactory. The experimental and clinical evidence were both strongly in favour of the disease being due to hyperthyroidism. The actual results of medical treatment could only be determined from the published statistics, and in the past these results had not been good. The mortality appeared to be about 25 per cent., and there was no question but that medical treatment often had to be prolonged over a course of many years. He was much interested to hear Dr. H. Mackenzie state that the results of medical treatment were unsatisfactory in some cases. This had been his own opinion, but it was based upon no direct evidence. Sir William Hale-White had given figures which at first sight appeared to favour medical treatment. His figures as published in his paper of 1912, if he interpreted them right, showed that only 102 cases were traced out of a total of over 200, and did not include a series of 18 that died in hospital. If this was so the results are valueless, for we had no knowledge of the mortality in the untraced cases. so that the total mortality might be anything from the 156 given by Sir William Hale-White to over 502. It was his custom never to operate in the first six months of the disease, for in this period the most beneficial results would be likely to accrue from other measures; thus every case upon which he had operated had been treated for six months or more, and many had been under treatment for as long as 10 to 15 years. His experience of these patients had been that while they were in bed having complete rest their condition was considerably improved; but that as soon as they were up and about again and attempted to work their disease relapsed, and that few, if any, had been able to live a normal life while undergoing treatment. He had found that the results of X ray treatment had been little, if any, better. He must admit, however, that, as in the case of medical treatment, it was mainly the failures that had come to him seeking further advice. His experience was based upon three groups of cases:—

(1) Eleven had come to him after X ray treatment, from which they had obtained little or no relief. Many of them had had treatment under different physicians for over a year. It was important to note that they came from all areas, so that it could not be claimed that the bad results were due to incorrect technique. All of them showed very considerable disfigurement from widespread telangiectases of the neck. Two stated definitely that while under X ray treatment their symptoms were greatly increased and that the thyroid became much more swollen. One of them developed carcinoma of the skin, which, although removed with a portion of the thyroid later, led to the death of the patient.

(2) Four which he operated upon in his early series relapsed after hemithyroidectomy, which he now knew to be insufficient. The symptoms were, as a rule, mild, and therefore they were especially suitable for X ray treatment. Although given a trial with this method they obtained no relief whatever.

(3) One was seen in the early stages when operation was considered inadvisable. In this patient the X rays were combined with medical treatment and the patient made a complete recovery.

It was his custom to advocate medical treatment:—

(1) In the first six months of the disease. During this period cases were transferred to a physician and the treatment usually consisted of rest, drugs, and X ray applications.

(2) As a preliminary to surgical treatment. As long as the patient was kept in bed and at complete rest very considerable improvement would follow, and no operation should ever be undertaken until such a preliminary course had been given.

(3) For certain cases where probably too small an amount of thyroid had been removed. They reached the third stage after operation, but failed to progress further. Medical treatment would then often help them to make a complete recovery. In all other cases operation is advocated.

In performing the operation he laid stress upon the importance of the following details.

Selection of the time of operation.—There could be no question but that the safety of the operative measures largely depended upon the careful selection of the time. Sometimes there were in the first six months or so very acute symptoms, and if an operation was then undertaken the mortality was likely to be high. With careful medical treatment the symptoms often abated, but having reached a more chronic stage failed to make further progress. It was in such a stage that the operation should be undertaken. All cases showed a very marked periodic variation. It would be noted, if a pulse and temperature chart were kept, that there were waves of exacerbation and depression, and that a period of exacerbation always follows any excitement, such as moving the patient to a hospital or nursing home. It was most essential that the operation be delayed until a period of depression of the symptoms. Hence no operation should ever be performed immediately after the patient had been moved to a hospital or home. He believed that two of the deaths in his early cases were directly due to the fact that he did not realise this important point. He had not found variation which had been described by Mayo, who stated that the best time to operate was either within the first six months or after the end of the first year, and that there was an exacerbation in the second six months, during which operation became a more risky procedure. In his experience if the patient were carefully watched operation could as successfully be undertaken during this period as in any other.

In the late stages of the disease secondary changes occurred, especially in the heart and kidneys. The mortality of operations undertaken in this period would be high, but with any other form of treatment the disease would steadily progress and the only hope of arresting its progress lay in operative treatment. The risk should therefore be carefully explained to the relatives, but operation should never be postponed because of these complications. He had one case where the disease had been in existence for eight years and very marked cardiac changes were present which quite incapacitated the patient from working. Since operation the man had improved enormously, and although the heart beat was still most irregular he was able to live a useful and happy life.

Selection of the type of disease.—There were three clinical types, two of which alone were true examples of exophthalmic goitre.

(1) The vascular type, which was most commonly seen in young women. The thyroid was large and there was much pulsation. There was a rapid pulse and well-marked exophthalmos. The chief complaint was dyspnœa and palpitation. Nervous symptoms might be present, but were not the chief factor in the disease. This type showed, as a rule, very good results after operation. The mortality was low and the progress after operation rapid.

(2) The nervous type, generally seen later in life and most commonly found in women at or about the menopause. The thyroid was often but little enlarged. Cardiac symptoms and exophthalmos were present, but not so obvious. The chief trouble was centred around the nervous system. The patient was very nervous, with tremors and erratic movements, so that she could hardly sit still, and her condition somewhat resembled chorea. The prognosis was less satisfactory. The mortality was slightly higher and improvement was slower. Some of them had definite mental symptoms; if there had been any form of mental disturbance before operation the mortality was likely to be much higher.

(3) Hyperthyroidism with adenoma. These were not examples of exophthalmic goitre at all, but were often included. There was a localised soft adenoma in one or other lobe which was associated with considerable evidence of hyperthyroidism, but never with complete hyperthyroidism. In no case so far had exophthalmos been present. These were the most satisfactory cases to operate upon. The mortality was negligible and the progress extremely rapid. The hyperthyroidism might cease completely within a fortnight after operation. It was often stated that the good results of surgical statistics were in large part due to the inclusion of many cases of this type. His series, however, did not include a single example of this variety.

It was important to remember the risk of operating for some other condition in a patient, the subject of hyperthyroidism. These patients seemed especially prone to gynæcological lesions, and he had seen a considerable number of cases with Dr. R. Andrews where the patient had been suffering with a uterine fibroid or some ovarian lesion. Operation elsewhere upon the body was associated with the same risk of increased hyperthyroidism without the relief gained by removal of a portion of the thyroid. For this reason he always advocated that wherever possible the thyroidectomy should be performed first. Later, when the condition was improved, the other operative measures could be carried out with relative safety.

Choice of operation.—The two chief dangers at operation were dependent upon pressure upon the gland and upon hæmorrhage. There was no doubt that if the hæmorrhage was severe the reaction after operation was much more marked. Owing to the dangers of pressure a wedge resection should never be performed. The portion of thyroid to be taken out should be removed by slow and careful dissection, all the vessels being ligatured before they were divided. He had never yet performed the operations of preliminary ligature or of injection of boiling water. By carefully selecting the time of operation the condition could be so improved that a partial thyroidectomy could be performed with safety. He was willing to admit, however, that some of the more severe cases could be much benefited by a preliminary ligature, and that it might render the later operation safer. He considered the operation of partial thyroidectomy to be the one of choice.

Preparation for operation.—Much of the success of the operation was dependent upon careful preparation of the patient. Stress had already been laid upon the importance of keeping these patients under medical treatment until their symptoms had abated. During this period it was his custom to have saline injections administered. They were given three-quarters of an hour before the time at which the operation would be carried out upon the appointed day. They seemed definitely to diminish the toxæmia and to lessen the symptoms. The choice of anæsthesia was extremely important. The evidence appeared to be convincing that there was real danger in the use of chloroform, and that the very high mortality which had been reported in the earlier series was dependent upon the use of this drug. Personally, he disliked operating upon patients under a local anæsthetic, and especially patients so extremely nervous. He believed that the anticipation of the operation might lead to an increase of the nervous symptoms. It was therefore his custom, wherever possible, to carry out the operation without the patient's knowledge. The relatives were informed but were asked not to communicate the fact to the patient. On the day of the operation the customary rectal saline was replaced by olive oil and ether, 3 ounces of each being given per rectum. Within half an hour the patient was quite unconscious and was then taken to the theatre. The dose was a minimal one and its effects were not sufficient to last through the operation; the anæsthesia was therefore continued with open ether, but as a rule only 1 or 1½ ounces was necessary.

After-treatment.—After describing his operative technique Mr. Walton said that after every operation there was a period of reaction which was probably due to hyperthyroidism following the trauma. The tube should therefore be kept in place *until* the temperature was normal. In one case in which it was accidentally removed too soon the patient had an acute attack of hyperthyroidism. It was rapidly reduced when the tube was re-inserted. On reaching the ward a rectal wash-out was given to remove the olive oil and ether and frequent rectal salines were given. If the patient was at all restless morphia was given without stint. No harm could arise if it was administered only when the patient was restless, and he had not uncommonly given as much as 2 gr. in separate ¼ g. doses within the first 24 hours.

Operative results.—Of the 101 cases there had been an immediate mortality of five. There was no question but that this was too high. Three of the deaths occurred within the first 50 cases, and two of them were almost certainly due to the operation being performed at an unsuitable time. Of those that recovered from the operation five have died later. One was due to an X ray carcinoma, and should not therefore be included. Two developed a fatal diabetes and two died with cardiac symptoms probably directly due to the hyperthyroidism. Of the remaining 91 cases 52 were cured, 23 had been so relieved that, although they still showed exophthalmos and a pulse which was considerably increased, were yet able to live normal lives and earn their own livings—that is, 75 per cent. had been changed from disabled wrecks into people who were capable of living normal lives and of earning their own living. Eight had had but slight relief and two were no better. They had developed marked hypertrophy of the remaining portion of the thyroid. Possibly, if they would consent, relief might be gained by further operative measures. Three had relapsed until their condition was nearly as bad as formerly, and three had been lost sight of. In considering the after-results of operation, it must be remembered that for a certain period the symptoms would continue, for the amount of thyroid removed had to be more or less empirical, and in order to be on the safe side rather too much was sometimes left. It was only when this diminished that the symptoms decreased. Careful observation after operation would show that the progress might be divided into the following stages:—

(1) The stage of reaction, which lasted for two or three days after operation. The hyperthyroidism was much increased, as shown by a raised temperature and pulse, and by marked restlessness. It was in this stage that a fatal result was likely.

(2) The primary improvement. This was the period which followed immediately after the reaction, and the improvement was often most remarkable. The exophthalmos might be diminished, the pulse, which had been 120 or 160 before operation, might fall to 80 or 90, and the nervous symptoms might abate enormously. It was a remarkable thing that many of the patients had shown a complete amenorrhœa for several years before operation, but during this period of primary recovery the catamenia might reappear and might be regarded as one of the first evidences of improvement. This stage persisted as a rule for two or three weeks.

(3) The stage of relapse. After the patients had left the home or hospital they suffered from a certain amount of relapse which might often cause considerable disappointment. If the case was progressing favourably it would last for only two or three months. Sometimes it might be prolonged for six or nine months, and if insufficient thyroid had been removed or if there had been much hypertrophy of the remaining portion the patient might continue in this stage. Those cases in which there had been little or no relief belonged to this group.

(4) The stage of apparent cure. This period, during which the patient was apparently well, but might relapse under any severe stress, might persist for two or three years. It was most in evidence during the war. Several of his patients who were apparently quite free from symptoms were exposed to air-raids, and within a short period of time had a very definite relapse of their symptoms.

(5) The stage of complete cure. This followed the last at an indefinite period. It was difficult to say when it had been entered upon, but apparently a time arrived after which the patient might be exposed to severe stress with no more fear of hyperthyroidism than would occur in a normal person.

The Basal Metabolism Test.

Professor H. G. **EARLE** said that for two months he had been using the basal metabolic test, which in theory was based upon the assumption that the thyroid sets the metabolic rate. With hyperthyroidism the metabolic rate was increased. He considered the test to be of value. By Benedict's apparatus, which he had been using recently, a direct measure could be obtained of the oxygen consumed. He had experienced great difficulty in taking the readings at first, but by means of an improvement whereby graphic records were obtained it was now possible to secure a very accurate measurement. The metabolic rate usually followed the pulse-rate, a high pulse-rate being generally accompanied by a high metabolic rate. There were other groups of cases, however, in which either a high metabolic rate was accompanied by a low degree of tachycardia or a low metabolic rate with a high degree of tachycardia. Cases with a high metabolic rate after a period of rest in bed were unfavourable for operation.

Mr. J. E. **ADAMS** said that the bad results of surgical treatment were in part due to the use of chloroform and want of gentle handling. A great merit of local anæsthesia was that it compelled gentle manipulation. Ether anæsthesia, per rectum, was a useful method, but the amount of ether necessary for removal of four-fifths of the gland was too great to be safe. He suggested that the introduction of radium into each pole of the remaining lobe, after hemithyroidectomy, might be advantageous. Frequently a patient was quite satisfied with the result of hemithyroidectomy and declined further operation.

Dr. F. **HERNAMAN-JOHNSON** was doubtful whether X rays, unless used in dangerous doses, produced definite diminution in the thyroid gland; yet beneficial results followed the use of X rays whenever applied. The good effects, he thought, were produced constitutionally rather than locally, and were general rather than specific. During treatment tram or 'bus journeys ought to be avoided and electrical methods should never be neglected. Proper radiological technique was as necessary as proper surgical technique. He now used X rays for their local regulating action as well as for their constitutional effect; the first could equally well be obtained by electrical treatment. In no sense were X rays an alternative or rival to surgery, for they should be used when the diagnosis was made, and in advanced cases were only useful to render the case more suitable for the surgeon. Though he agreed with almost everything that Dr. Stoney had said, he did not agree that X rays caused atrophy of the gland. It was, he thought, unjustifiable to show illustrations of telangiectasis of scarring or telangiectasis after X rays as arguments against their employment; the method was new, and these dangers had to be appreciated.

The discussion was further adjourned to March 4th at 5.30.

SECTION OF PSYCHIATRY.

MENTAL TESTS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 8th. In the absence of *Dr. Farquhar Buzzard, the President,* Dr. **PERCY SMITH** was in the chair.

Dr. W. A. **POTTS** read a paper on Mental Tests, which is published in full in the present issue of THE LANCET.

Discussion.

In opening the discussion, Dr. **PERCY SMITH**, that mental tests were very important, and that found the Binet-Simon series useful in dealing with children.

Dr. W. H. COUPLAND said that the great development of tests in America was important, even if the Americans were somewhat too enthusiastic in regard to them. In time the various tests would be more accurately evaluated. He agreed that the question of mental defect must not depend only on passing tests.

Dr. F. C. SHRUBSALL said that the subject was so vast that it was very difficult to criticise a paper dealing with it. The first point that occurred to him was whether 16 was the right age to take as the maximum limit of intelligence in connexion with the intelligence quotient; he rather thought it ought to be 13. If the mental age was below seven there was no chance of the defective doing much good. He did not think that moral tests were any use for moral imbeciles, because they always had satisfactory ideas in regard to what was right and wrong when anyone else was concerned. The unsatisfactory thing about them was their attitude to their own bad conduct. As regards the various series of mental tests, he could not agree that the Terman Revision was the best. He preferred the Binet-Simon, and was not sure that he did not like best the old Binet tests of 1908, because there was no reading test in them. The Terman Revision really dealt with a higher type than could be dealt with under the Acts dealing with defectives. Much depended on environment, and children of a better social position came out better in such tests. His opinion was that if defectives were not under the age of 9, according to the Binet scale, and if they could perform Healy's construction puzzles A and B, then they would manage quite well in the ordinary world. The paper had made very little reference to the Porteous maze tests, which he had found very useful. In tests such as the puzzle box or the wire test, the important point was not whether the person being examined could do the test himself straight off, but whether he could follow the steps when pointed out and done before him, and then be able to do it himself afterwards. He considered it important to test defectives along any special line of ability they might have.

SECTION OF OPHTHALMOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 11th, Dr. JAMES TAYLOR, the President, occupying the chair.

Commotio Retinæ with Extreme Œdema.

Mr. F. A. WILLIAMSON showed a boy, aged 15 years, who, six days previously, had received a blow in the eye from a suspended rope, immediately followed by loss of sight in that eye. He was first seen two days after the accident, and the œdema had since decreased a good deal. The macula was of a reddish-brown colour, and there were two horizontal folds in the retina. He raised the question as to whether the concussion alone could account for all the œdema present. When the eye became more quiet, some of the obscure features might be cleared up.—Mr. J. B. LAWFORD said that but for the definite time-association of the injury and the œdema he would have suspected that the concurrence of the two conditions was mere coincidence. If there had been rupture of any important vessel, the hæmorrhage would have been evident. The folding of the retina was very striking.—Mr. LESLIE PATON said that when he first saw the case it presented almost the typical picture of central embolism of the retina. It was still likely there might be blockage of a vessel, the result of the concussion, though he had never seen so much œdema as a result of simple commotio. There might be a tearing of a nerve which affected a vessel, and the hæmorrhage had not come forward.—Dr. G. MACKAY referred to a case which followed a blow from a tennis-ball, and agreed with Mr. Paton's suggestion on the present case.

Artificial Eyes and Lids Attached to Spectacle-Frames.

Mr. M. W. B. OLIVER and Mr. JACKSON, attached to the Sidcup Hospital for Deformities, gave a remarkable demonstration of facial improvement brought about by their imitation of the appearance of the normal eye on the spectacle-frame of those who during the war had received wounds of the orbit resulting in evisceration. They were highly commended by all the speakers.

Corneal Loop.—Scotometer.

Mr. BASIL T. LANG showed an ingenious corneal loop for removing, unaided, a foreign body from the cornea. At Mr. Holmes Spicer's suggestion he had added a transilluminator device.

Mr. LANG also demonstrated his Scotometer, for which ordinary unprepared paper could be used, and the observer could watch the patient the whole time. He reminded members of the important observations which could be made with the scotometer.

Mr. LANG read a paper on the subject of

Scotometry.

He said that in scotometry one was concerned with more or less blind areas surrounded by more or less healthy seeing retina, and was usually applied to areas within 40° of the fixation point. It only differed from perimetry in involving a more detailed examination. Two types of scotomata were recognised: absolute and relative, the latter when an area of the retina, while able to appreciate brightly lighted white objects, was unappreciative of certain colours or gray.

Among the points to be considered in determining the size of a scotoma were: illumination, size of the object, colour of the object, colour of the background, distance of the object, scale and size of the chart, and method of making the observations. If quite a small object were brilliantly illuminated, it might be visible over an area in which a less bright, but much larger object, could not be seen. In arriving at scotomata, therefore, the light used should not be too brilliant, and direct bright sunlight should be avoided, especially as natural light varied in intensity and colour with season. No standard of artificial illumination had yet been agreed upon, but that from a single carbon filament lamp was quite suitable for this purpose. The size of the object should be measured in terms of the angle it subtends, not by the length of the edge. If using a small object, the patient should be in the best position to see it, and if presbyopic, he should be wearing his correction. Green was less easily seen than red, red than blue, and blue than white. There should be a marked contrast between the colour of the object and the background, and the latter should not reflect light. The question of the distance at which the observations should be made was a controversial one, but if working very close to the patient it was difficult to move the object sufficiently slowly to give the patient time to form and convey his impressions. Quite accurate observations could be made at one-third of a metre distance. The scale and size of the chart were matters of personal convenience. There were many methods, and he laid it down that a good method should be easy to employ, should give accurate results, should enable a permanent record to be made easily, and should enable the observer to watch the patient during the whole examination to counteract eye wandering. He proceeded to describe and demonstrate his scotometer and to discuss the features of other makes. Possibly a patient with high hypermetropia might be the subject of increased intracranial pressure, and then arose the question whether the swelling of the disc was physiological or pathological. It was probably the former if the disc when determined with a dull green was no larger than with a brilliant white light. In some cases of tobacco amblyopia and of retrobulbar neuritis scotomata for green and red, or for green only, might be found, but the chief purpose of scotometry was to determine an increase of the blind spot in suspected glaucoma.

Mr. BISHOP HARMAN contended that it was an advantage to be unconscious of the progress of delineating the scotoma until it was completed, as the mind might otherwise be influenced by what was expected. Every effort should be made to exclude the personal equation, and that had been his aim in his own scotometer, which did also enable the observer to watch the patient.—Dr. A. H. H. SINCLAIR (Edinburgh) referred to the work of previous observers in this field especially Bjerrum, Runner, Walker (of Boston), Traquair (Edinburgh), and himself. All those observers realised the importance of using a very small test object. He thought the screen should be at a sufficient distance so to enlarge the scotoma that its details could be studied. The scotoma of interest in early diagnosis was the relative one.

Late Infection after Sclerostomy.

Mr. T. **HARRISON BUTLER** (Leamington) read a paper with this title. It opened with a historical sketch of the work of von Graefe, Grosz, La Grange (who discovered the first method which could be relied on to produce a filtering scar), Herbert, Evans and Allport, Holth, Freeland Fergus, and Elliot. Mr. Butler said the conclusion was that the modern fistulising operations were more efficient in reducing hypertension than was iridectomy, but that the danger of late infection was a serious offset which had deterred many from performing sclerostomy, driving them to older but less efficient procedures. He had himself treated 11 eyes, the subjects of such late infection, and some of the patients had had a second or a third attack. These tragedies caused him to abandon sclerostomy and revert to iridectomy; but the results of a series of cases were so futile that he reverted to trephining, and a comparison of his later results so completely vindicated the fistulising method that he did not propose again to perform iridectomy for glaucoma simplex. His statistics gave 45 per cent. of successful iridectomies, as against 75 per cent. of good results from sclerostomy.

During 1918–19 he trephined 40 eyes for glaucoma simplex, and until recently all had been successful. Two had reappeared with raised tension and had been trephined with success. On reviewing his cases over the last five years, he found all the late infections had followed the trephine operation and Holth's punch operation. He discussed a number of informing cases in detail. It was obvious, he said, that the scar left by the punch was far more vulnerable than was the trephine scar; probably there was more bruising. A button-hole was a serious menace, but in some cases the conjunctiva was so friable that it might tear. The Holth operation belorged to the past. He thought hypertony was one of the conditions favouring late infection. In many of his unfavourable cases alcohol had been a factor. When he knew *Staphylococcus albus* was obtainable from the conjunctival sac he refused to operate. In order to avoid late infection, he thought the operation should not be regarded as an easy one; a perfect technique should be cultivated, and, consistent with good work, the operation should be done as quickly as possible; the flap should include all the tissues, and should not be bruised. Any local septic focus should be searched for. As an antiseptic lotion for use all the time, he advised a 1 in 10,000 solution of oxy-cyanide of mercury, used nightly in an eye-bath.

Mr. S. H. **BROWNING** asked whether the eyes were examined bacteriologically before operation, and, if so, by what method. If by Elschnig's method, that did not receive general approval. Pneumococcal infections in the eye were quite common. The presence of pus was apt to be deceptive, and should not be the only thing looked for, as eyes apparently healthy were found to contain pneumococci, streptococci, and even *Staphylococcus aureus*, in numbers to warrant postponement of the operation.—Mr. D. **LEIGHTON DAVIES** (Newport) emphasised the importance of a sufficiently thick flap; a thin one might lead to late infection.—Mr. M. S. **MAYOU** agreed that a thick flap was an important protection against infection. Another protection was the amount of fluid leaking from the anterior chamber through the trephine hole. He had had only one case of late infection after trephining; he had seen two others, and in all recovery was good.

Mr. **BUTLER**, in reply, agreed as to the adoption of good methods of ascertaining whether the conjunctival sac was sterile, but for practical purposes he used a 48-hour culture on agar.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—A special meeting of this society was held in Manchester on Feb. 24th to discuss a proposal to make the society a constituent part of the Tuberculosis Group within the Society of Medical Officers of Health. A majority of those present were in favour of maintaining independence for the discussion of purely clinical matters, leaving any who wished to do so to join the new group. Decision was deferred until after a meeting with a deputation from the M.O.H. Society to be held in Liverpool on April 7th.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF STATE MEDICINE.

AT a meeting of this section on Jan. 14th Dr. R. J. **ROWLETTE**, the President, opened a discussion on

Medical Reform in Ireland.

He gave an abstract of a recent report of the Irish Public Health Council and expressed the opinion that it gave the foundation for a thorough and statesmanlike scheme of reform. Unfortunately the Government had declined to legislate on it, and the Chief Secretary had given contradictory reasons for this refusal. The scheme might, however, form the basis of legislative action when a normal system of Government would again exist in Ireland. It was a hopeful sign that those who represented the political opinions of the majority of the Irish people had serious and sound views on health matters.

Sir **JOHN MOORE**, President of the Academy, read a paper on

Existing Hindrances to Public Health Work in Ireland,

in which he drew attention to the fact that the Infectious Disease (Notification) Act of 1889 provided that the local authority should pay to the medical practitioner a fee of 2*s.* 6*d.* for each certificate sent by him in accordance with the Act if the case occurred in his private practice. This provision was endorsed and extended by the Infectious Diseases (Prevention) Act of 1890. The Tuberculosis Prevention (Ireland) Act of 1908 provided that a fee of 1*s.* should be paid to the practitioner for certificates in the case of persons treated in public institutions, and 2*s.* 6*d.* if the case occurred elsewhere. The Local Government Emergency Act of 1916 *reduced* the fee payable for notification to 1*s.* in all cases. With regard to the sanatorium treatment of tuberculosis, he referred to the extraordinary fact that an impasse between the Local Government Board and the local authorities should be allowed to cause serious risk to public health by interfering with and interrupting the machinery provided under Statute for dealing with tuberculosis. Lastly, he pointed out that the recommendations and proposals of the Irish Public Health Council, a statutory body, had been for the time being stultified by the decision of the Government that schemes involving expenditure and not yet in operation were to remain in abeyance.

Mr. T. A. **BURKE** congratulated Dr. Rowlette and Sir John Moore on their very radical and fearless treatment regarding the backwardness and existing obstacles generally of public health administration in Ireland. It was very hopeful to see medical men of the political views and professional standing of Sir John Moore and Dr. Rowlette putting Irish public health before every consideration. It was gratifying and hopeful to see that such pioneers of public health in this country were so unmistakable in attaching responsibility to the British Government for the threatened (actual in some places) suspension of the health services in Ireland. The present deplorable condition of public health in Ireland was for the most part due to the Government withholding grants which heretofore were given towards public health administration, but now were diverted to meet the awards for malicious injuries.

Dr. T. G. **MOORHEAD** said that he had been lately studying the financial position of the voluntary hospitals, and that he was of the opinion that the only hope for the future lay in some form of State subsidy or grant. He hoped that the voluntary basis would always be maintained. He saw little prospect of a sufficient increase in voluntary subscriptions to meet in any way the present difficulties. For the last year or so most of the hospitals had succeeded in getting a larger percentage of the patients to pay than heretofore, and in the future, undoubtedly, considerable sums would be obtained from the patients, but there would still remain a considerable number of people in the country who would be quite unable to pay their way when ill, and he hoped that the hospitals would never shut their doors to this class. When the combined sums of voluntary subscriptions, pay from patients, and municipal subscriptions were added together there would still remain a deficit, and this deficit he felt must be made good by the State. Even if this were done it was not necessary to have State control. The municipalities that subscribed to the hospitals sent representatives to the hospital boards. These representatives were, as a rule, most welcome and were most useful members. Similar representatives of the State would, he felt sure, add strength in every way to the hospital boards in the future.

Sir WILLIAM THOMPSON, Registrar-General, said as a member of the Irish Public Health Council he did not think even the profession fully realised the amount of invaluable work done for public health by Sir John Moore, Dr. Rowlette, and Dr. Alice Barry, who were selected by the Irish medical profession to represent their interests on the Irish Public Health Council. As might be expected, such representatives of the profession did not confine their efforts to protecting and promoting in any narrow sense the mere worldly interests of the profession; some of the best features of the report of the Irish Public Health Council were due to the incorporation of the suggestions of the three medical representatives whose names he had just mentioned.

Dr. H. T. BEWLEY, Dr. W. M. CROFTON, Dr. H. M. EUSTACE, Dr. G. NESBITT, Mr. E. P. MCLOUGHLIN, and Dr. T. HENNESSY also spoke.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.

A MEETING of this society was held at 122, Harley-street, on Feb. 14th, Dr. JANE WALKER, the President, being in the chair, when the office-bearers for 1921 were elected as follows:—President: Dr. Jane Walker. Secretary and Treasurer: Dr. P. W. Edwards, Bramcote Sanatorium, Nuneaton. Executive Committee: Dr. H. O. Blanford, Dr. Esther Carling, Sir Henry Gauvain, Dr. Marcus Paterson, Dr. S. Vere Pearson, Dr. Niven Robertson, Dr. James Watt, and Dr. R. C. Wingfield.

Dr. JAMES WATT opened a discussion on

A Scheme of Sickness Insurance for Ex-sanatorium Patients.

The need of after-care was, he said, well recognised, but it was hopeless at present to expect the State to subsidise the civilian ex-patient. The scheme of insurance outlined took account of the great liability to relapse, but applied only to a limited class—those whose working capacity was quite, or almost completely, restored by treatment. It must be purely voluntary, should impose no extra burden on the employer, and be independent of, and a supplement to, National Health Insurance. It could be best applied to a group of tuberculous persons employed in an institution or in a business, or even possibly to a group of persons scattered through many businesses, in which case the after-care committee might administer the fund. The main idea was that a group of tuberculous persons employed by an institution or in a business should form themselves into a benefit club, managed jointly by themselves and the employer, to the funds of which the members would contribute by weekly deductions from wages when in health, and from which they would draw during temporary breakdown of health sufficient benefit to maintain themselves and their dependents. Various safeguards to keep the fund solvent and to prevent disputes were described, and it was suggested that a premium of not more than 10 per cent. of wages would suffice to cover all sickness due to tuberculosis where reasonably suitable cases were selected. A large number of ex-sanatorium patients would willingly join such an insurance scheme, since it would considerably increase their employability and diminish the risks of a further breakdown in health.

Dr. H. A. ELLIS compared the scheme with that for Post Office employees. It would succeed only where good cases were picked. If a man's relapse was taken early it cost only a few pounds to put him on his feet again, and if he survived two years without relapse he was quite a good life. The keynote in employing ex-sanatorium patients was to put them on repetition work.

Dr. F. R. WALTERS thought the plan might succeed for a combination of institutions or businesses. The period during which benefit was paid would have to be limited, because where a tuberculous person broke down it was for very long periods.

The discussion was continued by the PRESIDENT, Dr. G. HEATHCOTE, Dr. PATERSON, Dr. BLANFORD, Dr. CARLING, Dr. W. GOODCHILD, Dr. A. C. TA'BOIS, Dr. NOEL BARDSWELL, and Dr. W. T. GORDON PUGH. A committee was finally appointed to investigate the sickness-rate in institutions employing tuberculous staff, and to formulate recommendations.

The report of the committee on

Standards of Staff (Medical and Nursing)

in sanatoriums and tuberculosis hospitals was submitted and adopted. The committee was requested to report further on the modifications necessary in the case of the staff of small institutions and of hospitals for non-pulmonary forms of tuberculosis, and on the standards of domestic and clerical staffs for the different types of institution. The report adopted recommended that for a sanatorium or hospital for advanced cases there be one medical officer, including the superintendent, for every 75 beds where the dispensing and the bacteriological work are not done by the medical staff, and one to 70 where they are. The standard laid down for nursing staff, including the matron, is one for every eight beds in a sanatorium, and one for every five beds in a hospital, on the basis of a 56-hour working week. The best nursing unit under one sister was 50 beds in a sanatorium and 40 beds in a hospital.

Consideration was resumed of the report of the committee on the

Coördination of Statistics.

The main part, dealing with the classification of cases of pulmonary tuberculosis had been referred back to the committee.[1] It was decided to adopt the Ministry of Health's proposed classification of immediate results of treatment—namely, arrested (where quiescent for at least two years), quiescent (including absence of T.B. from sputum), much improved, no material improvement. As to after-results, these should be described thus: fit for full work (being the person's ordinary occupation), fit for light or partial work, unfit for any work, died, lost sight of. It was agreed to postpone the question of the symbolic representation of physical signs, and to make no recommendation regarding the form of case records.

---

[1] This report was presented by Dr. Niven Robertson at a meeting of the society held on Dec. 13th. It was urged that uniform methods should be agreed upon for classifying cases of pulmonary tuberculosis and for describing the immediate and the after-results of treatment. Classification should be based on the four main factors influencing prognosis—namely, anatomical extent of lesion, type of lesion, systemic effect, and presence or absence of tubercle bacilli in sputum. The upper and middle lobes of the right lung should be regarded as one lobe, which would then be comparable in size with the other three lobes. Extent of disease in the lung, along with tuberculous lesions of other organs, should be divided into four groups, while four types of lesion were proposed depending on presence of infiltration, consolidation, excavation, and fibrosis. Systemic effect was divided into three grades depending on the degree of the main symptoms. Finally cases were to be further sorted according as tubercle bacilli had or had not been found in the sputum. This method of classification would mean a large number of groups, but would provide an accurate and scientific sorting of all cases of pulmonary tuberculosis where large numbers were being dealt with. For small numbers it was preferable to use a simpler method, dividing cases into early, medium, and advanced. On the motion of Dr. James Watt this report was referred back to the committee with the instruction to work out a system of classification which should fit into that proposed by the Ministry of Health, and which should be further subdivided in a way similar to, but improving upon, that of the American Sanatorium Association. The Ministry, he said, were putting forward a classification, which, after a primary sorting according to sex and presence or absence of tubercle bacilli, divided the T.B.-positive cases into three groups, depending mainly on the grade of constitutional disturbance, thus separating off on the one hand the undoubted sanatorium cases, and on the other the undoubted hospital cases from a large heterogeneous middle group. For institution purposes this middle group, and possibly also the others, would require subdivision. While the degree of systemic effect must be taken into account in classification, the primary factor should be the extent and character of the tuberculous lesion. The method of the American Sanatorium Association divided these two main factors each into three classes, giving nine groups in all, a number which was convenient for clinical as distinct from public health purposes, and which could probably be made to fit into the Ministry's classification. The committee was also asked to give consideration to the classification proposed by the Inter-departmental Committee.

The meeting adopted the report of the committee on the

Training of Nurses,

which advises a two years' training in a tuberculosis institution, followed by an examination conducted by an independent examiner and to the satisfaction of the College of Nursing. Nurses should be encouraged to proceed to general training, from which a remission of six months in a three years' training should be allowed to those passing the examination.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING was held on Feb. 15th at the Elizabeth Garrett Anderson Hospital, Mrs. E. Flemming, M.D., in the chair, when Dr. Eva Handley-Read read a paper on

The Influence of Diet on Dentition

(1) on teeth during the pre-natal period, (2) on dental caries, (3) on pyorrhœa alveolaris.

The speaker emphasised the importance of accessory food factors as absolutely essential to growth, and of the antirachitic fat-soluble A vitamine as a necessity in diet if the hardest tissue of the body and the one requiring the best nourishment—i.e., the enamel of the teeth—is to develop properly. Dr. Handley-Read said that the temporary teeth are fully formed in the jaws before birth. Calcification begins in the sixteenth week, and continues throughout the existence of the teeth; hence it is evident that the mother's mode of living during pregnancy and lactation must influence the teeth of the child. Even at the worst war period the diet of the poorest working women of this country had just sufficient essential vitamines to produce bone and tooth tissue fairly well calcified, and observations at baby clinics, &c., showed that the teeth of all babies erupt fully formed with apparently good enamel, but if the diet is poor in the antirachitic vitamine the enamel is found carious within a few months. Dr. Harriette Chick, Mrs. Mary Mellanby, and others had done much important research work on the accessory food factors. It had been shown that absence of fat-soluble A influences the development of teeth and jaw in puppies, causing (1) poor growth of bone and alveolar process, the tissue being osteoid; (2) irregularity of lower incisors; (3) delayed eruption and shedding; (4) delay in calcification, poor enamel and dentine, and lessened resistance to diseases such as distemper and broncho-pneumonia. Pregnant and nursing mothers should thus have a liberal supply of fat-soluble A in the diet as well as the other vitamines.

Dr. Handley-Read referred to the work of Dr. Sims Wallace, Sir F. Colyer, and Dr. J. Wheatley on the importance of stone-ground flour in diet owing to its antineuritic vitamine, to cellulose content, and to its need of attrition. Vigorous mastication stimulates the flow of saliva essential for proper cleansing of the mouth and for the neutralisation of acids. Speaking of the infant's diet after weaning, she said that the transition from milk to solid food should not be via pap food as this is bolted without proper mastication or insalivation. By 1½ years of age, if dentition is normal, a child should be able to masticate an apple, while from 2–5 years a normal child should be capable of masticating any hard food. The County Council classes in their syllabus advised a diet which was almost entirely confined to pap food and yet insisted on the importance of efficient mastication. It was interesting to note that between 1919 and 1920, according to Dr. Wheatley's report from Shropshire, children of 5 years of age showed on an average 1·9 decayed teeth per child, as against 6·4 per child between 1910 and 1914. This seemed to be explained largely by the restriction in the purchase of carbohydrates, and by the fact that new bread was prohibited and crusts of coarse bread had to be eaten. In poor districts ½*d.* worth of raw carrot (a vegetable particularly rich in vitamines) largely replaced the pre-war pennyworth of sweets.

Pyorrhœa alveolaris was now rampant all over the world among white and coloured races, and was also common in animals kept in captivity. It seemed probable that excessive carbohydrate and deficient antiscorbutic diet largely accounted for this. In true scurvy acute periodontitis was a marked symptom and the teeth dropped out if antiscorbutic treatment was delayed. Probably modern diet contained sufficient antiscorbutics to prevent actual acute scurvy but not to prevent a chronic periodontitis. Pyorrhœa was present because in the mouth there was damaged tissue in the shape of inflamed gums, due to pap foods; bacteria were always present and with a diet deficient in antiscorbutic vitamines pyorrhœa supervened. That many vegetarians suffered from pyorrhœa was probably explained by the fact that they are mostly large consumers of carbohydrates and that their vegetables or fruit are rarely eaten raw. In Asiatic races caries is rare, but the teeth drop out at middle age in those parts of the country where the antiscorbutic factor is deficient in the diet. Points which lead to the conclusion that chronic general periodontitis was really connected with diet were its universality, its development among wild animals brought into captivity, the fact that no specific bacteria had been isolated, and the further fact that some persons who might be considered food cranks had effected their own cure.

Dr. Handley-Read then described several cases in which she had found acute pyorrhœa which had completely cleared up on a diet of raw vegetables, salads and fruit, eggs, a little *milk, and very limited carbohydrates. An "intensive vitamine"* diet such as this would produce astonishingly good results. While firmly believing in the efficacy of such treatment for chronic pyorrhœa, local treatment by drugs, vaccines, and ionisation should not be neglected.

In the discussion of the paper Dr. O. Lewin, Dr. D. Hare, Dr. E. Harding, Mrs. Flemming, and others took part.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

AT a recent meeting of this society Dr. G. Caussade and Dr. P. Charpy communicated a paper on the

Pharmacology, Posology, and Clinical Aspects of Salicylate of Soda.

They remarked that the toxicity of this drug had been much disputed. While fatal cases had been reported after small doses, in other instances only transient disturbances had been caused by much stronger doses. Children above the age of 7 would very well take the doses ordered for adults; on the other hand, above 30 the drug was usually contra-indicated because, in the first place, acute articular rheumatism was rare after that age; and secondly, because the liver and kidneys were less likely to be healthy then than in younger persons. Women showed a special susceptibility to the drug, and it should not be given to alcoholic subjects or to persons with a nervous taint. Apart from individual susceptibility, the impurity of the product employed should be considered. Commercial salicylate of soda contained free salicylic acid, isomeric acids, isophthalic and creosotic acids. The last two were toxic substances, and every salicylate should be rejected which was not crystalline, and which was violet or grey in colour and acid in reaction. Salicylate of soda was mainly eliminated in the urine in the form of salicyl-uric acid, a *combination* of salicylic acid and glycocoll. Its elimination should be hastened by putting all patients taking the drug on a vegetarian diet, since by that means a more abundant formation of glycocoll was effected, the suppression of which might give rise to serious symptoms. The most frequent, if not the most serious, symptom of salicylate intoxication was delirium. It appeared fairly soon after the commencement of treatment. Its onset might be sudden, occurring at the same time as the pains in the joints disappeared. When it developed less suddenly it was characterised by talkativeness, restlessness, and a freedom of movements in striking contrast with the functional impotence of the previous days.

Dr. Gaston Durand read a paper on

Migraine and Auto-hæmotherapy,

in which he reported the case of a woman who at the age of 50 began to suffer from attacks of migraine accompanied by urticaria, which became worse in the course of six months until she had only a few days' respite. After other methods had failed Durand decided to make use of autohæmotherapy which he had found successful in several cases of urticaria. A subcutaneous injection of 10 c.cm. of the patient's blood was given during an attack, and four days later at the onset of an attack, with the result that the patient for the first time for three months was a whole fortnight without having another attack. The next attack was mild and the subsequent ones milder still, 2 c.cm. of the patient's blood being used on each occasion. During the following months only abortive attacks occurred, and were easily cured by injections of 2 c.cm. of the patient's blood.

Dr. G. Petges (Bordeaux), in a paper on

The Treatment of Epidemic Hiccough by Aspirin,

stated that in several cases he had found that aspirin in doses of 1 g. had a very rapid and successful action on the hiccough, and for that reason he was inclined to regard the condition, not as a manifestation of influenza, as had been done by Logre and Heuyer, nor of epidemic encephalitis, as maintained by Sicard and Paraf and Achard and Rovillard, but as a rheumatoid or rheumatismal manifestation.

Dr. G. LEVEN, in his paper on

Symptomatic Aerophagia,

stated that although the diagnosis of aerophagia was an easy matter, the practitioner should realise that the most typical aerophagia might sometimes accompany an organic lesion, and that the most careful and complete treatment of aerophagia might fail because the symptoms masked a more serious disease. He recorded three typical cases of aerophagia which were associated with descending goitre, stricture of the œsophagus, and cardiac hypertrophy respectively, these three diseases being to a certain extent responsible for aggravating the aerophagia.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A MEETING was held at the Royal Devon and Exeter Hospital on Feb. 17th, Mr. A. C. ROPER being in the chair.

Mr. A. L. CANDLER showed: (*a*) X ray plate of a case of Perthes or Legg's Disease of Hip in a girl aged 17, who also gave evidence of deficiency of endocrine glands; (*b*) Myoma of Uterus weighing 10½ lb. with pregnancy of four months' duration; (*c*) three specimens of Ectopic Gestation—viz., tubal, ovarian, and secondary abdominal pregnancies.

Mr. NORMAN LOCK showed: (*a*) Two Ribs with Chondrosarcoma on the Inner Side removed successfully some months previously; (*b*) Large Stones in Kidney; (*c*) a greatly Thickened Gall-bladder containing a Gall-stone.

Dr. RANSOM PICKARD exhibited Eyes removed for Sarcoma of Choroid and Sarcoma of the Ciliary Region respectively.

Dr. G. P. HAWKER showed a patient with Embolism of Retinal Artery.

Dr. R. V. SOLLY showed: microscopic slides of (1) Cattle and other Ringworms; (2) Basal-celled Carcinoma; (3) Cerebral Tumour in Brain secondary to Sarcoma of Eye in a case where no other secondary growths could be found elsewhere at the autopsy.

Dr. SOLLY also showed for Mr. B. DYBALL: (1) Myeloma of *Fibula; (2) Hypernephroma.*

Dr. F. A. ROPER showed X ray photographs of: (1) Osteitis Deformans with commencing Sarcoma; (2) Hernia of Stomach into Left Side of Thorax following G.S.W.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

Exhibition of Cases and Specimens.

A MEETING was held at Liverpool on Feb. 18th, Mr. CARLTON OLDFIELD, the President, in the chair.

Dr. J. E. GEMMELL and Dr. LEYLAND ROBINSON showed three specimens of Uterine Fibroids, complicated in two cases by a coexisting carcinoma of the body of the uterus. In the third specimen a left hæmatosalpinx was present and was evidently produced by torsion, as there was no evidence of ectopic pregnancy.

Dr. J. H. WILLETT and Dr. R. A. HENDRY (Liverpool) showed a specimen of Hydatidiform Mole with a Well-developed Four and a Half Months' Fœtus and Placenta. They were of opinion that this was a case of twin pregnancy in which one ovum had undergone vesicular degeneration.

Dr. W. W. KING (Sheffield) described a case where acute symptoms arose during pregnancy from the rupture of a vein on the surface of a subperitoneal myoma of the uterus. At the operation a large quantity of free blood was found in the peritoneal cavity. The tumour was removed by myomectomy and the pregnancy left undisturbed.

A discussion took place on Dr. F. H. Lacey's paper on Induction of Labour for Moderate Contraction of the Pelvis, read at the last meeting of the society and reported in THE LANCET, Feb. 12th. The opinion of the majority of the speakers was that, although excellent results could, no doubt, be obtained in hospital, as Dr. Lacey's figures showed, the method was extremely tedious in private practice and apt to cause a good deal of anxiety to the patient and her attendant. Cæsarean section should be the operation of choice where there was any reason to fear that delivery of a healthy full-term child by the natural passages was going to be ble.

Reviews and Notices of Books.

TRUTH ABOUT VENEREAL DISEASE.

By MARIE CARMICHAEL STOPES, D.Sc., Ph.D. London: G. P. Putnam's Sons, Ltd. 1921. Pp. 52. 1s. 6*d*.

TRUTH, unfortunately, is a relative term. In regard to venereal diseases it has suffered very greatly at the hands of its most eager disciples. Mrs. Stopes has visited both warring camps—she acknowledges indebtedness for much information from Mrs. A. C. Gotto and also from Mr. H. Wansey Bayly—and has discovered as common to both the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease a body of ascertainable facts, some simple deductions from these facts, and campaigning principles based on these deductions. These are set forth with great literary skill and persuasiveness in a little pamphlet of 50 pages, which, she states, was written at the request or with the approval of Professor W. M. Bayliss, Sir James Crichton-Browne, and others. The book is divided into nine sections, of which the headings are: Germs Generate Disease; The Deadliest Germs; Pure and Happy Marriage is the Only True Safeguard of the Race; The Characteristics of the Deadliest of all Germs; Contact is the Source of Infection; Disinfectants do Disinfect; Disinfectants Only Disinfect; Disinfectants Disinfect, They do not Cure; Humanity can be Entirely Freed from this Terror. While the first eight sections are instructive it is to the ninth that the informed reader, sick of controversy, will naturally turn. Mrs. Stopes holds that if we only dealt with the subject energetically enough we should stamp out the diseases in this country more quickly and easily than plague, small-pox, or leprosy. To this end she is assured of the necessity of a complete survey of everyone in the country, although it may be many years before the public demands it. Sex diseases, she thinks, would never have saddled themselves on humanity had not all *sex knowledge been befouled by prudery.* "No one would willingly sleep with a case of small-pox or the plague." She believes that a new and overwhelming spiritual power is even now entering upon the earth, but that immediately to stem the onrush of contamination some *new factor* of health and cleanliness must be brought into play during the hiatus, until the young generation grows to maturity. The concluding paragraph of the book runs:

> It is the duty of the Churches to win the people by moral precepts and teaching to a right view of life and pure living; it is the duty of the doctor to see that people are decently clean; it is the duty of the reformer to see that people *know* facts essential to their life and progress. In this respect the moralist and the doctor have essentially the same message to teach.

We believe that the chief merit of Dr. Stopes's book lies in the fact that after reading it every right-minded citizen will enlist according to his strength and ability in the campaign against venereal diseases, and will be unlikely to embarrass the high command by violent adhesion to a particular battalion.

LECTURES ON DISEASES OF CHILDREN.

Fourth edition. By ROBERT HUTCHISON, M.D., F.R.C.P. London: Edward Arnold. 1920. Illustrated. Pp. 416. 21*s*.

AN author who publishes in book form a series of lectures prescribes for himself definite limitations, by which the writer of a text-book is unfettered. Each lecture must be a composite whole, even though the teaching be in accordance with consecutive tenets or theories, and the subject-matter of its title must stand out in relief. Though necessarily hampered by these restrictions, Dr. Hutchison has contrived to embody in his lectures a great deal of information of first-rate importance concerning the diseases of children, and it is not to be wondered at that a fourth edition has already been called for. The author has rewritten the lectures dealing with infant feeding, tuberculosis, and congenital syphilis, added a new lecture on fever of obscure origin, making 31 lectures all told; and he has revised the remainder.

We could wish that the question of breast-feeding had been less summarily dealt with. Its importance is recognised, but, we think, scarcely emphasised enough, nor are its advantages forcibly expounded to the uninitiated. Its many pitfalls, too, receive scant notice, and though various devices are advocated by which premature weaning may be avoided, the reader is given no guiding principle by which to select the treatment. Due regard is paid to weight as an evidence of the infant's progress or the reverse, but we think that the other criteria are rejected somewhat lightly, no distinction being made between such doubtful evidence as is procurable from a history, and objective signs of malnutrition other than those afforded by the scales. In the matter of bottle-feeding the author makes many recommendations with which divers authorities would disagree; this is only to be expected in so contentious a field. Thus, he disapproves of dilution of milk by more than one-half, yet delays the giving of whole milk until the ninth month. Again, though he endorses the modern practice of feeding infants less frequently, by advising three-hourly feeds from the beginning, he postpones four-hourly feeds until the sixth month. His dictum that "a good mixed milk from a trustworthy dairy is all you need" is, no doubt, excellent; but unfortunately the good mixed milk and the trustworthy dairy are hard to come by, except in favoured and limited areas. With the milk-supply in its present state Grade A certified milk deserves mention, for therein lies the only safe alternative to dried milk in many districts.

A new lecture on fever of obscure origin is one of great practical value, and a welcome addition to the book. In it are discussed the several conditions which may cause in children fever the origin of which is difficult to find or remains undetermined, but the occurrence of which is frequently a matter of great concern to the parents and practitioner alike.

Briefly, the book is a sound, lucid, and attractive exposition of the more important parts of pediatrics, and has this notable virtue—it is entirely free from fads.

Practical Preventive Medicine.

By Mark F. Boyd, M.D., M.S., C.P.H. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 352. 20s.

An author who aims at summarising the whole field of modern industrial medicine in just over 300 pages, many of which are devoted to illustrations, is attempting an impossible task, and Professor M. F. Boyd has hardly done justice to himself or his subject. He makes free use of the modern American plan of presenting subject matter by the method of classification; this is occasionally effective in his hands, but more often oppresses the reader with multiplicity of detail. Preventive medicine depends upon the broad principles of health, and the student who finds himself faced with a vast array of pigeon-holes, each containing, neatly docketed within, a compact list of facts, will never obtain a right sense of proportion. This book may almost be accused of being useful for examination purposes, an accusation which is no compliment to the examination system. Most textbooks are uneven because authors are not contented to deal only with their own specialty, but attempt to present the specialties of others. Such books take their value from those chapters which arise from the special knowledge of the author. Perusal of the book under review has failed to disclose any subject so handled, and we find ourselves in agreement with the preface, that "no originality is claimed for the material here presented."

There are, however, readers who like to absorb knowledge in tabloid form, and to them we recommend this book, for the facts stated are correct and up to date. Professor Boyd has given lists of references at the end of each chapter which are most valuable to us, since they refer to many sources of information published in America and not known in this country; but we should have expected his American readers to desire information regarding literature published abroad. If so, they will be disappointed that only American publications are named, for public health medicine saw its birth in this country, and continental workers have contributed nourishment to the growing child.

Madura Foot.

Dos Mycetomas. By Dr. Alex K. Yazbek. Published by the Faculty of Medicine and Surgery of S. Paulo. 1920. Pp. 164.

This monograph, which is based on a study of seven cases of "madura foot," deals with a condition unfamiliar to European practitioners. The disease is, nevertheless, of importance in its relation to actinomycosis, which is now being more frequently recognised than hitherto in this country. No condition resembling madura foot has yet been recorded in England, but there is no inherent impossibility that it may not one day be found, for Dr. Yazbek considers that he has identified the infective agent as *Discomyces bovis* in four of his seven cases. This treatise is well illustrated with photographs of microscopic preparations, cultures, and typical lesions; from the latter it is evident that the condition bears a close clinical resemblance to actinomycosis as found in other parts of the body. The treatment appears to be unsatisfactory. The infective agent is not always the same; iodide medication is sometimes ineffectual and amputation may have to be performed.

Diseases of the Ear.

Second edition. By Philip D. Kerrison, Aural Surgeon to the Willard Parker Hospital for Infectious Diseases. London and Philadelphia: J. B. Lippincott Company. 1921. With 332 illustrations and 2 coloured plates. Pp. 596. 35s.

This book, by reason of its size, is intended less for the medical student and general practitioner than for the student of otology, who will find it a most interesting, useful, and instructive work. The teaching is sound and practical, and the statement of controversial matters is very well balanced. The author has devoted more attention than is usual to suppurative labyrinthitis and to the cerebral complications of aural disease, and the chapters on these subjects are the best in the book. It would have been a more orderly arrangement if the caloric and rotation tests of the labyrinthine function had been described together with the examination of the hearing in the preliminary chapters, and not placed among the symptoms of suppurative labyrinthitis; for it is not only in this disease that the labyrinthine tests are of value. Similarly, Bárány's tests of cerebellar function might have been considered with the testing of the ear, instead of having a chapter to themselves. But these are minor matters, and the book may be cordially recommended to all who desire a sound and thorough knowledge of otology. The illustrations, the type, and the paper are all excellent, and there is a good index.

Practical Bazaar Medicines.

With over 200 Useful Prescriptions. By G. T. Birdwood, M.A., M.D. Cantab., Lieutenant-Colonel, I.M.S. Calcutta and Simla: Thacker, Spink, and Co. 1920. Pp. 179. Rs.3/8.

This little book is written for the use of medical men working in Indian districts far away from chemists' shops, and points out how many maladies can be treated inexpensively and efficiently by means of drugs obtained from the bazaars. It begins with a list of bazaar medicines classified according to their actions; the bulk of the work consists of two sections, of which one deals with the sources, actions, and methods of use of the more common and useful bazaar remedies, and the other forms a bazaar medicine pharmacopœia comprising more than 200 prescriptions. The book will be found especially helpful as a reminder to medical men that many simple remedies already known to h habitually used by them, can be obtained in the with regard to the less-known native difficulty arises in that prescribers, at any rate those trained in England, have no adequate means of ascertaining the genuineness and purity of such products. A few of the formulæ are open to criticism; "Pot. chlor.," named as an ingredient of Rogers's intravenous injection for cholera, is ambiguous; one would expect an ointment consisting of catechu, wax, and honey to present some difficulty to the compounder, and, on paper at least, a mixture of catechu, chalk, alum, ferrous sulphate, and gall-nut powder as a dentifrice appears rather nauseous. The book, which is interleaved with blank pages, should prove distinctly useful to those for whom it is intended.

JOURNALS.

The Journal of Biological Chemistry (Vol. XIV., 1920) contains a number of useful studies on vitamines, of which the following may be specially mentioned:—

A Deficiency in Heat-treated Milks (p. 381), by A. L. Daniels and R. Loughlin.—The authors obtained no data indicating that either the fat-soluble or the water-soluble vitamine in milk is affected by heat treatment, nor is the casein apparently affected. The results of all the experiments pointed to the one conclusion that long-heated and super-heated milk owes its deficiency to the fact that in the heating process the calcium salts are rendered more or less insoluble. Rats fed on such milk make inferior growth, but normal growth-gains were made when the heated milk was supplemented with calcium phosphate properly incorporated. The application of these findings to infant nutrition is now under investigation.

A Quantitative Method for the Determination of Vitamine in Connexion with Determinations of Vitamine in Glandular and other Tissues (p. 531), by F. K. Swoboda.—The biological test of Williams for the detection of small quantities of the water-soluble B vitamine was developed and found to be of quantitative value. From the results of determinations of the vitamine-content of various organs it is evident that this specific vitamine is present in large quantities in most of the organs of internal secretion which are of developmental importance, whereas there was a very much lower concentration in other organs examined. The liver and kidneys, however, are high in vitamine-content, whereas tissues high in nuclear material—e.g., thymus and lymph glands—gave low values.

Water-Soluble B in Cabbage and Onion (p. 175), by B. K. Whipple.—The yeast-growth method (Williams) was used. Although quantitative results were not secured the following points were established. Water-soluble B in cabbage is not destroyed by boiling for 30 or 60 minutes, neither is it destroyed by boiling with acid or alkali. It is present in onions and is not destroyed by boiling. Not more than one-half the water-soluble B is lost in the cooking water from cabbage or onions boiled for 30 minutes.

The Effect of Cooking on the Water-Soluble Vitamine in Carrots and Navy Beans (p. 158), by E. W. Miller.—The yeast method used for the quantitative determination of the vitamine content of vegetables has yielded good results when averages were taken of the number of colonies. Cooking carrots at 100° C. for 30 minutes, or heating them when tightly packed in a jar for 45 minutes at 115° C. causes no reduction of vitamine. Cooking Navy beans at 120° C. for 30 minutes decreased the vitamine content 40·6 per cent.; cooking for 70 minutes in 0·5 per cent. sodium bicarbonate solutins caused a loss of 37·5 per cent. of the vitamine. A large proportion of the vitamine from 36 to 70 per cent. was present in the cooking water.

Some Effects of Water-Soluble Vitamine upon Nutrition (p. 255), by W. G. Karr.—From experimental observations the author concludes that a relation exists in the dog between the desire to partake of food and the amount of the so-called water-soluble B vitamine ingested. Brewers' and bakers' yeast, tomatoes and milk were investigated as sources of vitamine B. Quantitative data are given to show the relative potency of the various substances investigated. Brewers' yeast was much more potent than bakers' yeast. Drying at 100° C. does not appreciably lower the vitamine content of these supplements, but heating in an autoclave at 120° C. for three to four hours causes destruction.

Metabolism Studies with Diets Deficient in Water-Soluble B Vitamine (p. 277), by W. G. Karr.—The lack of the water-soluble accessory does not affect the utilisation of nitrogen or metabolism of the dog. Data are presented which show that small amounts of a *good* protein (casein or yeast) beneficially supplements proteins which are known not to be so complete (wheat gluten).

A Test for Anti-Beri-beri Vitamine and its Practical Application (p. 457), by C. Funk and H. E. Dubin.—The procedure is as follows: A yeast suspension is prepared by shaking a loopful of a 48 hours' pure culture of yeast in 100 c.cm. of Nägeli solution on a shaking machine for three hours. Measured quantities are incubated for 20 hours at 30° C. in the presence of the unknown vitamine, with control tubes containing a vitamine of measured strength. The fermentation is stopped by heating the tubes to 75° C. in a water-bath for a few minutes, the contents transferred to special centrifuge tubes, and the volume of yeast estimated after centrifugalisation for 15 minutes. The approximate vitamine activity of a number of products has been determined by this method and the activity of autolysed yeast under various conditions has been observed.

Nutritive Properties of Milk, with special reference to Reproduction in the Albino Rat (p. 157), by H. A. Mattill and R. E. Conklin.—Young rats, taken at weaning, were placed on various rations consisting primarily of cow's milk, fresh and desiccated. The rations included the addition of starch, wheat embryo, dry skim milk, butter fat, and iron citrate, but a ration containing dry milk and 1 per cent. yeast was the only one on which normal growth and successful reproduction were obtained, and the growth of rats on that ration and one containing 5 per cent. of yeast was normal.

Reference may also be made to a series of articles dealing with Blood and Urine Analysis.

Note on the Preservation of Specimens of Blood Intended for Blood-Sugar Determinations (p. 203), by W. Denis and H. Aldrich.—The relative rapid decrease in the sugar content of the blood, occurring even when preserved at low temperatures, can be prevented by the addition of 1 drop of commercial formalin (40 per cent. formaldehyde) to 5 c.cm. of oxalated blood. The addition of a larger amount of formalin (3 drops to 5 c.cm. blood) adds no advantage, nor apparently does it introduce any error in the determination of sugar by the Folin-Wu method (Ibid., 1920, xli., 367). By this method of preservation glycolysis in blood specimens can be prevented for as long as 96 hours at temperatures varying from 20° to 33° C.

Rapid Colorimetric Methods for the Determination of Phosphorus in Urine and Blood (p. 55), by R. D. Bell and E. A. Doisy.—The method depends on the fact that certain reducing reagents will reduce phosphomolybdic acid without affecting molybdic acid. Phosphomolybdic acid is reduced by hydroquinone, giving a blue colour, which is distinct even with as little as 0·005 mg. of phosphorus as phosphate in a volume of 100 c.cm. The method is rapid and easy of manipulation. Details are given for the determination of inorganic, organic, and total phosphorus in the urine, and inorganic and acid-soluble phosphorus in the blood. The method for inorganic phosphate appears to be more accurate and rapid than the usual uranium titration.

The Estimation of the Chlorides in Blood (p. 47), by V. C. Meyers and J. J. Short.—A method for chloride estimation in blood is described; the proteins are removed by precipitation with picric acid, and the chlorides estimated by the Volhard-Harvey method in the filtrate. The picric acid filtrate can also be used for the estimation of creatinine and sugar.

The Nature of Chlorine Combination in Urine (p. 239), by A. T. Cameron and M. S. Hollenberg.—These authors conclude that, in the absence of chlorate or similar medication, chlorine occurs in the urine as chloride only; organic chloride and chlorine oxy acids are absent.

Estimation of Phenolic Substances in Urine (p. 409), by T. F. Tisdill.—The results obtained for the total phenolic substances in urine by the ether extraction method outlined in this paper are at least 50 per cent. lower than those recorded by Folin and Denis. It is suggested that there are unidentified substances present in urine which react with the colour reagent used by Folin and his co-workers, which are responsible for the high values by the latter method. These unidentified compounds are partly present in the free state and partly formed by the action of strong minerals acids on the urine. Only a small fraction of the volatile phenols are excreted in the urine in the free state.

British Journal of Experimental Pathology. February, 1921. London: H. K. Lewis and Co. *7s. 6d.*—The Measurement of Capillary Blood Pressure in Man, by Leonard Hill, F.R.S., and J. M. McQueen. The pressure which stops the flow through and expresses blood from the skin has generally been taken as the measure of the capillary blood pressure. It indicates actually the pressure in the small arteries plus the pressure required to deform the convex horny layer of the skin. The authors have devised a method for estimating the true pressure of the small arteries; it amounts, they find, to 10 mm. of mercury. Results obtained by Dr. Hill and his collaborators in previous investigations into capillary pressure in the brain, in transparent membranes in frogs and mice are given and discussed. They all indicate that the true capillary pressure is very low, a fact of great importance in physiological theories of lymph secretion, and bearing directly upon our conception of inflammation.—Spontaneous and Artificial Pulmonary Lesions in Guinea-pigs, Rabbits, and Mice, by H. B. Maitland, Mary L. Cowan, and H. K. Detweiler. A pulmonary lesion, which is an agonal phenomenon, is described, characterised by hæmorrhage into the alveoli and sometimes into the bronchioles, without leucocytic infiltration in the lung tissue. A second type of lesion consists in a slow proliferation of endothelial cells.—The Nature of the Effect of Blood Pigment upon the Growth of *B. influenzæ*, by P. Fildes. The author concludes that the blood pigment acts as a catalytic agent.

Ophthalmic Literature. Denver, Colorado: Ophthalmic Publishing Company. Published quarterly.—Up till the end of 1919 a digest of ophthalmic literature was published monthly as a supplement to the *American Journal of Ophthalmology.* The subjects of the 12 supplements were so arranged that each number dealt with certain topics, reviewing the literature in connexion therewith for the preceding year, the 12 supplements being separately paged, and forming the "Ophthalmic Year Book" for each year. In 1920 a new method of publication was adopted without any alteration in the plan of the subject matter. Instead of monthly supplements a separate number is published quarterly under the title of "Ophthalmic Literature," the four numbers forming, as before, a complete digest of the ophthalmic literature of the world for the 12 months preceding their date of publication. It continues to be issued as a supplement to the *American Journal of Ophthalmology,* and is delivered free to the subscribers to that journal. The work is excellently done by eight editors, with 25 collaborators, all but four being Americans. It forms by far the most complete digest of recent work in ophthalmology all over the world.

THE LANCET.

LONDON: SATURDAY, MARCH 5, 1921.

Records and Medical Secrecy.

THE general question of the law in its relation to medical secrecy is under the consideration of the Lord Chancellor, but Dr. ADDISON replied last week to two specific questions put to him by Colonel F. E. FREMANTLE on behalf of colleagues inside and outside the House of Commons. The first related to the possible liability of a doctor to an action for libel in respect of matter entered on an insurance record card should this be "published" to his private secretary. The Minister of Health said he was advised that in the circumstances mentioned it was in the highest degree unlikely that there would be any cause of action against the doctor unless malice on his part could be proved. It is indeed not very easy to imagine conditions which would lead to any such action being ever attempted. True, there may be technical publication of defamatory matter, but no one will know that such matter has been so published unless the doctor or his secretary chooses to give information about it. Even should the secretary be cast for melodrama and say to the patient, "My employer has entered on a card that you are suffering from a certain disease, involving disgraceful conduct on your part, and has handed the card to me for filing," the fact that the entry was true and was made in accordance with a statutory regulation would be a complete answer to any proceedings for libel or slander. If, on the other hand, a wrong entry were made designedly the medical man who suffered for so doing would deserve no sympathy. If he made an error of diagnosis, or had a lapse of memory, the absence of malice, referred to by the Minister of Health, would help him out, although privilege accorded in terms by Parliament might protect him more completely.

A second question referred to the possible obligation to produce medical history cards under subpœna in a court of law. Here Dr. ADDISON'S reply was to some extent evasive. He appears to have suggested that in any case the facts desired to be proved would have to be the subject of oral evidence. This, however, would not protect the medical man from being requested to look at his entry on a card and so to refresh his memory or correct his statement. To this extent, therefore, the enforced production of the cards in court might be the means of extracting from medical men information on confidential matters adversely affecting their patients. We need hardly say that if a medical man is called on behalf of a patient, it is his duty to say what he knows, and the question of what he has written on a card will not affect his desire to do so. It is with regard to evidence which is adverse to the patient's interest, and which, if given, will be given without the patient's authority that we are more concerned. Such evidence is an old matter of controversy, frequently disputed between the medical man summoned into the witness-box on the one side and counsel or the court on the other. The question here is to what extent will the possible production of past medical history cards operate with regard to the giving of medical evidence under order of the court by an unwilling witness. We are inclined to think that it should have little or no effect.

If a medical man gives evidence, willingly or not, he will give it truthfully and accurately, and will acknowledge where his memory is at fault. In such circumstances he, at any rate, has nothing to fear from the production of the cards. When we consider whether the patient will have anything to complain of we must remember the conditions under which adverse medical evidence may come to be given in the case of insured patients. It appears to us that, if the patient is interested in establishing the truth, the medical man who has attended him will almost inevitably be a witness on his side. If he is not going to be called on behalf of his patient, but subpœnaed against him, the doctor may be reluctant to give evidence, and has a right to express his reluctance. He can hardly desire, however, to keep silence from "ethical" reasons, if he knows that his patient, relying on his silence, is endeavouring to deceive a court of law and to defeat justice. In such a case as we have suggested can a patient rightly complain if a medical record, made at the time by his panel doctor, helps to establish the truth? We are inclined to think not, and to believe that, as a general rule, any danger from the production of cards in court, if they are made producible, will only affect an inaccurate witness or a dishonest suitor. That there may be exceptions is possible. These will be cases, however, where the medical man will protest against giving evidence, and invite the protection of the court. The ruling given will not depend upon the production of the cards under discussion.

◆

The Report on Biologicals.[1]

WE published last week a resume of the conclusions arrived at in the report of the strong Departmental Committee appointed by the Minister of Health to consider the effective control of therapeutic substances which cannot be tested by direct chemical means. On the analogy of "chemicals" we propose, for want of a better term, to call these substances "biologicals." We found the conclusions arrived at reasonable, and at the same time referred to the fact that they had been discredited in the daily press upon the issue of the report. The medical correspondent of the *Times* has provided a case in point. We are certain that the *Times*, like ourselves, have the dissemination of accurate information at heart, and we welcome the coöperation of the general press, which has latterly done so much to explain the medical position in public affairs to thousands who could not be expected to read scientific journals, or to accept the views expressed in such quarters; but the divergence of opinion between the medical correspondent of the *Times* and ourselves is in the matter of this report so open that we owe it to our readers to justify our views. They are prompted by intimate knowledge of the origin of the report, and of the value of the evidence upon which its recommendations have been based.

The comments by the medical correspondent of the *Times* appeared on Feb. 23rd, and show no close acquaintance with the Report, and also no desire to consider it on its merits. No attempt is made to appreciate the position which led to the Committee's appointment, or the problems with respect to which they were asked to make recommendations. It is stated that, "so far as can be ascertained," the General Medical Council, which is the body responsible for the British Pharmacopœia, have performed their duties well, and might, if necessity exists, have their powers extended—the implication being that the further safeguards suggested by the Committee are superfluous. Now it was part of the Committee's duty to interrogate the representative (the President) of the General Medical Council, and to inquire what had been the action of the Council with regard to biologicals. The Committee were informed that the Pharmacopœia Committee of the General Medical Council had been unable to include in the Pharmacopœia precisely the important remedies of the class referred to the Committee, because they were not susceptible to such tests for activity and authenticity as were regarded necessary in the Pharmacopœia. The Pharmacopœia was obliged to prescribe such tests as could be carried out by a qualified pharmacist, by a public analyst, or by some public functionary, such as the Government Chemist. In the case of the remedies under consideration, no such tests could be prescribed, and no public provision was made for the performance of the only possible tests. Accordingly, in 1909 the President of the General Medical Council approached the Government with the suggestion of a public institution for the pharmacological standardisation of potent drugs and of serums, an action which disposes of the view that the admirable work of the Council could be extended to perform the work which they admitted to be necessary.

---

[1] Ministry of Health. Report of Department Committee on Control of Certain Therapeutic Substances. London: His Majesty's Stationery Office. 1921. 2*d*. net.

We cannot find any suggestion in the Report "that the sera and vaccines supplied by the great drug houses, and by such institutions as St. Mary's Hospital, will be much improved by control and inspection," while it would appear that the medical correspondent of the *Times*, in writing thus, has overlooked the cited evidence of important manufacturers. There exist in this country no standards for biologicals to which manufacturers or scientific institutions can work. The country has been fortunate in that the preparation of these substances has been for the most part in the hands of well-qualified, and responsible workers, but there is nothing to prevent its falling by competition into hands of a very different kind. There is with us no restriction on importation, and no kind of guarantee that importers will have regard to the standards which British manufacturers have adopted for themselves. The case of salvarsan illustrates the anomaly of the present position very clearly. Before the war this substance was entirely obtained from Germany. It is admittedly extremely dangerous to use preparations of it which have not been tested by biological methods to ensure their freedom from toxicity. During the war an emergency control was obtained by the roundabout method of inserting into every licence for suspension of the patent rights held by German nationals a clause imposing the obligation to have every batch which was manufactured tested before issue by a proper authority. Now that war is finished this control over the British-made product will shortly come to an end, while the German product is again being freely imported without control of any kind, except what is exercised in the country of its origin. Medical opinion is clear that the situation is a dangerous one. Is it to continue because effective control necessitates legislative action? We should find such economy very like carelessness.

The Committee, in drawing up their recommendations, had several possibilities to consider. It was urged from some quarters that the simple way out was manufacture by the Government, and free distribution. The Committee, on grounds of efficiency and economy, promptly rejected this suggestion, which was indeed excluded by implication from the terms of their reference. Another possibility would have been to adopt a proposal, such as that put forward in 1909 by the General Medical Council, for the establishment of a new public institution with Government money, where the necessary standardisation could be carried out. This also is rejected in the Committee's Report. After considering the working of the different systems, whether of Government monopoly or official control—some of which already exist in other countries—the Committee decided to recommend a scheme which should enable the Government to deal with the whole matter without creating a new institution. They point to the fact that, in the clearly imperative case of salvarsan, biological control has already for some years been carried out by the scientific staff of the Medical Research Council in their National Institute for Medical Research. They suggest that the Medical Research Council should be asked to undertake the duty of preparing such other biological standards as are required; that as far as possible the application of those standards should normally be left to the individual manufacturers; and that the minimum of inspection necessary to see that the standards are faithfully and properly applied shall be carried out by the scientific workers themselves, who have the responsibility for the preparation and maintenance. The legal authority for scheduling the substances which need such control, is to be, not the Minister of Health nor any Committee appointed by him, but the already existing Committee of the Privy Council to which the Medical Research Council are already responsible for the discharge of their existing functions. The Committee were presented with a problem which asked urgently for action, and they seem to have found a way of dealing with it efficiently, at little expense to the public, and with the minimum of interruption to conscientious and efficient manufacture. The manufacturers, indeed, are strongly in favour of the scheme as giving them, as well as the public, protection from the activities of those who are inefficient or dishonest, or both.

BRADFORD TECHNICAL COLLEGE: COURSE IN PUBLIC HEALTH.—A course designed to meet the needs of qualified medical practitioners who may wish to obtain the Diploma in Public Health of the Royal Colleges of Physicians of London and Surgeons of England has been arranged by the Technical College Committee and the Health Committee of the City Council. For this purpose the Technical College has recently been placed upon the list of recognised institutions by the Royal Colleges. The proposed course will extend over 25 weeks, and will include lectures and laboratory work in bacteriology and pathology and in chemistry. The course in bacteriology will be conducted in the Public Health Laboratories. Dr. William Campbell has been appointed lecturer in bacteriology and the pathology of industrial diseases, and Dr. R. Cecil Robertson assistant lecturer and demonstrator in serology and immunology. The course in chemistry will be conducted in the Chemical Laboratories of the Technical College, under the direction of Dr. R. D. Abell.

Annotations.

"Ne quid nimis."

THE FELLOWSHIP OF THE ROYAL SOCIETY.

IN scientific circles the elections to the Fellowship of the Royal Society are scanned with a keen and jealous eye, to judge which sections or sub-section may claim the largest share of this coveted honour. Medicine is fortunate in that she can justly count in her list those who bear any part in the teaching of medical students, or whose work has intimate relation to medical research. Of those recently selected the physicists, Professor W. L. Bragg and Professor W. H. Eccles; the biologists, Dr. W. G. Agar, Dr. W. T. Calman, and Dr. A. H. Church; and the chemists, Professor K. J. P. Orton and Professor J. C. Philip can certainly be placed in these categories, while the services of Mr. G. U. Yule and his fellow statisticians, already invaluable, will be requisitioned to a still greater extent as medicine becomes a more exact science. The qualified medical men include a distinguished ophthalmologist, Mr. J. H. Parsons, while pathology and bacteriology are well represented in the persons of Professor Georges Dreyer and Dr. J. C. G. Ledingham. No one of these needs introduction to readers of THE LANCET. Professor Dreyer's recent work on the measurement of vital capacity and of normal basal metabolism has appeared in our columns, and within the last few weeks Dr. Ledingham has published a valuable contribution to our knowledge of cultural diagnosis. We congratulate these new Fellows in the name of all their colleagues in the teaching and in the scientific practice of medicine.

THE FULL USE OF ARTIFICIAL LIMBS.

THE letter from Dr. M. Dockrell in THE LANCET of Feb. 19th raises the important questions: To what extent are patients who have suffered amputation able, by the light of nature, to use the limbs with which they are provided, and how great is their disability when properly fitted? Other questions also demanding a reply are: Can these patients be benefited by physical treatment? Is this treatment perfected? Is it procurable? Familiarity is presumed with the pioneer work of Captain Rowlatt Maxwell, C.F., amongst men who have undergone upper-extremity amputation. Provided the patient will make the effort required to use his prosthesis, instead of relying upon the remaining limb to do the work of both, he can gain great help from his appliance, although considerable disability must needs remain. Amputation of a lower limb, on the other hand, should entail little or no disability provided that 4 inches of bone are left; with less than this, disability becomes pronounced. Yet there are many patients with above-knee amputations, and even some with below-knee, who use their artificial limbs so indifferently that their handicap is severe alike in work and play. This should not be. The ordinary method of training—namely, to place the patient in his limb and instruct him to walk up and down prepared slopes and so forth—is inadequate. Some may learn the full possibilities of their limb by the light of nature; few are so fortunate. For the latter a special course of training was devised at St. Thomas's Hospital, which provided accommodation for a certain number of limbless officers at the request of the Ministry of Pensions. Here it was found that even for above-knee amputations the patient should not be incapacitated, whatever his walk or station in life. The mining engineer, the traveller, or the golf professional should be able to return to his duties or his recreations. Training is supported by the knowledge that the blind tabetic is not ataxic until the last stage of his disease, while many tabetics with good vision can be trained until their disability is negligible. It was surmised that patients with amputations should be better off than the tabetic, as joint- and muscle-sense are intact in the remainder of the limb, however small, and common sensation can be educated to a pitch of efficiency which largely compensates for the lack of feeling in the artificial part of the limb. And this was found in practice to be true. Dancing, jumping, walking naturally up and down stairs are all within the scope of practical possibilities, but only, for the most part, as the result of careful training. Dr. Dockrell has indicated the value of muscle-training for below-knee amputations. Naturally, the importance is greater the higher the amputation. But more important still is the education of joint, muscle, and common tactile sensations. These can be developed until the patient can actually feel with his artificial foot sufficiently to recognise its position on the ground or in space, and can detect any trifling irregularity of surface. Full efficiency cannot be restored unless the patient is fitted with a limb sufficiently light in weight to enable him to use it without fatigue either of muscle or sensation. Fortunately the controversy over the relative merits of the light and heavy limb is now a thing of the past, although comparatively few of the light-metal limbs have so far been issued. But adequate training is essential if the best use is to be made even of these limbs, and it should be available for the many. The so-called training, as at present in vogue, is inadequate; muscle-training and education of the various senses are imperative if full success is to be attained. To accomplish this every muscle which controls the movements of the remaining joints needs to be fully developed by special exercise and training, and their coordination re-developed to meet the alteration of function required of them. Not only have these muscles to learn the control of the joints on which they act directly, but also that of the artificial joints in the distal part of the limb. The use of "harness" of the central knee control type is a confession of inability to train the muscles which govern hip movement to control that of the artificial knee. Yet this training is practicable in almost every case, and the patient thereby saved from unnecessary apparatus and from the compulsion of using muscles other than those intended by nature for the purpose of walking. Efficiently to carry out the necessary training presupposes an intimate knowledge of muscle action, of joint movement, of the nature and function of all common and special sensation, and experience in training modelled on the lines originally laid down by Fränckel. To entrust this highly specialised work to an orderly, a nurse, or even to a medical gymnast, who has not been specially trained in work of this description, is to deprive patients of the full benefit of their limb. The difficulty of securing competent instructors is a real one, but not insuperable if those in authority recognise the need.

THE SUSPENSION STABILITY OF BLOOD CELLS IN PULMONARY TUBERCULOSIS.

IN 1917 Fahraeus showed that in pregnancy and certain diseases the blood cells in a column of blood gravitate to the lower sections of the column more quickly than under ordinary conditions. In *Beiträge zur Klinik der Tuberkulose* (1921, Bd. xlvi., Hft. 2) his countryman, Dr. Alf. Westergren, publishes a series of investigations on 500 persons, most of whom were inmates of a Stockholm tuberculosis hospital. His technique was as follows. A "Record" syringe of about 1·2 c.cm. capacity was used, and one-fifth of its space filled with a 3·8 per cent. solution of sodium citrate. A vein of one arm was then punctured and the syringe completely filled with blood. This was then shaken up in a small test-tube and then aspirated into a cylindrical glass pipette, with a capacity of about 1 c.cm. and a height of 200 mm. This pipette was kept vertical, and after an hour the length of the column of clear plasma was read off. After carrying out more than 3000 such tests Dr. Westergren found that the rate of sedimentation varied from 1–2 to as much as 120 mm. in the hour. The rate in a normal person was about 2 mm. per hour, and it was regarded as definitely pathological when it was 10 mm. or more. In the case of tuberculosis the suspension stability of the blood was inversely proportional to the activity of the disease. When the rate of sedimentation was within the normal limits there were also no clinical signs of active disease, and the prognosis, as judged by the clinical evidence, was good. In some afebrile cases the normal stability of the blood was much impaired, and the opinion was formed that this test was a much more reliable index to the degree of activity of the disease than the patient's temperature. The rate of sedimentation was invariably increased by fever, particularly when this was due to tuberculosis; and it was noted that a febrile period was often preceded by an increased rate of sedimentation. This test is, however, certainly not specific; in addition to pregnancy and acute infectious diseases, Bright's disease, syphilis, certain forms of "rheumatism," diseases of the blood, and other conditions may greatly hasten the rate of sedimentation. The test would, therefore, seem to be of less value in diagnosis than in determining the degree of activity of tuberculosis and its prognosis.

FIFTIETH ANNUAL MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE fiftieth annual meeting of the American Public Health Association will be held in New York City in November next. The date which is tentatively announced is Nov. 14th–18th. It is especially interesting to ourselves to note that Dr. Stephen Smith, the founder and first President of the Association, who is now entering his ninety-ninth year, is expected to celebrate his approaching centennial, together with the semi-centennial of the Association. Dr. Smith was for many years one of our correspondents in America. The first organisation meeting of the Association was held in New York City on April 18th, 1872, and that is one of the reasons for selecting the same place for the celebration of the semi-centennial. Other considerations are the convenience to foreign representatives and to Dr. Smith, who lives in New York City. Moreover, a plan will then be feasible to conduct demonstrations of public health methods in the laboratories, executive offices, garbage disposal plants, and similar centres of public health interest, where New York City is often a model of administration. It is expected to present in connexion with the celebration a review of the progress of the various branches of public health within the last 50 years. The sectional programmes will include Public Health Administration, Vital Statistics, Laboratory, Food and Drugs, Sociology, Sanitary Engineering, Industrial Hygiene, and Child Hygiene.

CARCINOMA OF THE STOMACH IN A BOY.

Dr. D. A. Laird,[1] of Edinburgh, records the case of a boy, aged 15, with an unimportant hereditary and personal history, who was admitted to hospital for pain in the chest and back of a fortnight's duration, with occasional vomiting. On admission a small, hard, epigastric swelling was found just medial to the left costal margin. There was no tenderness, but a dull pain was complained of over the swelling, radiating to the left scapula. The liver was enlarged and tender. On examination of the blood leucocytosis was found. Both test-meal and vomit showed an absence of free hydrochloric acid. Nothing was found on X ray examination. Seventeen days after admission to hospital laparotomy was performed by Professor Alexis Thomson, who found an inoperable tumour of the lesser curvature of the stomach, with secondary nodules in the liver. Glands were excised from the mesentery for examination and the abdomen was closed. The operation was followed by temporary improvement, but death took place four weeks later, only two months after the onset of the first symptoms. The tumour, which on microscopical examination proved to be a columnar-celled carcinoma, was found at the autopsy to involve the whole of the lesser curvature of the stomach, and the entire posterior wall medial to the cardiac orifice as far as the greater curvature. Perforation of the stomach had occurred shortly before death, as the peritoneal cavity showed gastric contents but no signs inflammatory reaction. Metastases were found in the liver, pancreas, diaphragm, and the gastric, pyloric, aortic, and mediastinal lymphatic glands. Commenting on the case, Dr. Laird draws attention to the sex of the patient, showing that the great majority of recorded cases of carcinoma of the stomach under 30 have occurred in males, though it may be noted that a case under Sir Norman Moore was in a girl aged 13. Other noticeable features in the present case are the rapid course characteristic of the disease in young subjects, the temporary improvement after laparotomy, which is not infrequent in inoperable carcinomata, and the rare metastatic involvement of the diaphragm.

EXPENSIVE ECONOMY.

THE intention of the London County Council to withdraw its annual grant to the Physiological Laboratory of the University of London, and the consequent decision of the Senate to close the laboratory "failing the assurance of adequate support before the end of March, 1921," threaten a disaster, the extent of which our readers will realise. The laboratory is the only institution in the United Kingdom where the requirements of elementary teaching do not to some extent interfere with the development of research work, and the prospect of deprivation of the facilities for original investigation, which have proved valuable to many workers in physiology, has occasioned strong protest. The Senate have given as a second reason for their resolve, the fact that more space is required for general university purposes, while the London County Council is presumably expecting shortly to have to contribute largely to the establishment of the University on a new site. But whatever the future demand upon space, it is surely worth while to leave the laboratory *in situ* for what can only be a comparatively short period of time; and the grant of £500 a year now made by the Council does not seem large in view of the expense of the removal of the University already contemplated, and is very small in proportion to the scientific value of the work done. It is to be hoped that the Council will reconsider its decision, and that the Senate, if they cannot see their way to let the laboratory remain in its present quarters, will, at any rate, take steps to house it elsewhere. At a recent meeting of the Medical Faculty of the University resolutions were passed urging the continuance of the work, preferably at the Imperial Institute, and suggesting that, failing the support of the Council, the Senate should allow a sum of £1300 for the triennium ending in August, 1924, even if a portion of that sum has to be taken from the reserve fund of the University. The reserve fund is reported to stand at a considerable figure; but if assistance from this quarter should remain lacking it is almost impossible to believe that some private individual or corporate body will not come forward with the means necessary to ward off what would be a deserved reproach to public intelligence.

CZECHO-SLOVAK MEDICAL COMMISSION.

ON Feb. 18th, at the Czecho-Slovak Legation, the members of the Commission gave to representatives of the press their impressions of a visit to this country, which terminated officially on Feb. 24th. The members of the Commission, who were officials of the Czecho-Slovakian Ministry of Public Health and Physical Education, said they had studied the English and American systems rather from the point of view of public hygiene and sanitation than from that of medicine. Comparing the English and American services they expressed the opinion that the former, with its combination of central and local control, was more suited for adaptation to the needs of their own country. They were accustomed to State organisation—the old Austrian system had been completely centralised and very uneconomical—and nothing in England had impressed them more than the voluntary hospitals. They had obtained much valuable information in matters of school hygiene and child welfare generally, including pre-natal care and milk control; the milk shortage in Czecho-Slovakia was at present a source of great difficulty. A movement was already on foot in that country to group districts together for the more comprehensive treatment of tuberculosis and venereal diseases; in the matter of the education of medical officers of health and lay health visitors they hoped to follow the English example. Their public health officials were only allowed to enter the service after two years' ordinary practice; hitherto, moreover, no body comparable to the English health visitors had been organised. Water-supply and housing had also attracted the special attention of the Commission. With regard to physical education in Czecho-Slovakia, it was remarked that a law would shortly be enacted making compulsory a system of training for men up to the age of 21—i.e., up to the beginning of the period of military service. All townships, &c., would be required to provide and maintain space and apparatus for the working of this national scheme. The compulsion was not extended to girls, but the "Sokol" Athletic Association, with branches all over the country, was awakening widespread interest in the physical development of both sexes. Questioned as to the expense of the projected reorganisation of public health services in Czecho-Slovakia, Dr. Karel Driml, who acted as interpreter, explained that the State would bear the entire cost, and that the impoverished condition of the country would make it necessary to move slowly. In conclusion, members of the Commission expressed the gratification afforded them by the cordiality of their reception in this country, and whilst regretting the short duration of their visit and the resultant limitation of their movements, they hoped that the contact thus established with English medical and public health institutions would be maintained with mutual advantage. They wished particularly to mention with gratitude the name of Dr. J. A. Glover, of the Ministry of Health, who had acted as their guide throughout the visit and had given them every possible assistance.

---

[1] Edinburgh Medical Journal, February, 1921.

RUPTURE OF SYPHILITIC PAPILLARY MUSCLE.

A CASE of a very rare accident—rupture of a papillary muscle of the heart—has recently been reported by E. D. Spalding and W. C. Von Glahn.[1] A coloured labourer, aged 31 years, was admitted to the City Hospital, Baltimore, on March 23rd, 1920. There was a history of a venereal sore in 1905 and of a miscarriage of his wife. Fifteen months before admission he had an attack of hoarseness for three weeks, after which he suffered from dyspnœa and nocturnal cough with bloody sputum. This subsided spontaneously, but returned more severely a year later, when he was admitted to the University of Maryland Hospital on Jan. 5th, 1920. The apex beat was in the sixth interspace 14 cm. to the left, where an indefinite presystolic thrill was felt. There was a diffuse præcordial heave. At the apex the sounds were replaced by a blowing systolic and short diastolic murmur. At the base and down the sternum a short diastolic murmur replaced the aortic second sound. The second pulmonic sound was accentuated. There was slight dullness at the base of the right lung behind, and the liver extended three finger-breadths below the ribs. Blood examination showed slight secondary anæmia and a positive Wassermann reaction. The X rays revealed an enlarged heart and aorta and clouding at the base of the right lung. Compensation was gradually restored, and he was discharged on Feb. 27th. He steadily went down hill, and after a month was admitted to the City Hospital. He was œdematous and dyspnœic. The pulse was rather rapid and collapsing but regular, and of fair quality. He did not appear to be in a bad condition, and was given a bath in the ward. Immediately afterwards he complained of feeling ill. He was cyanotic, sweating, and very dyspnœic with rapid, thin, and weak pulse. He was wheeled to his bed, and three minutes later was frothing at the mouth and nose. The heart was found greatly dilated, chiefly to the left. Venesection was immediately done, strophanthin administered intravenously, and morphine and atropine subcutaneously. The pulse became stronger, but the respirations were slow and very laboured, with tracheal rhonchi. He was turned on his face and artificial respiration performed, but he soon died. The diagnosis was aortic and acute myocardial insufficiency due to syphilis. The necropsy showed a greatly hypertrophied heart, chronic passive congestion of the viscera, and œdema of the lungs. The cavity of the left ventricle was much enlarged, measuring 12 cm. from mitral ring to apex. The posterior papillary muscle was Y-shaped, being divided into two pillars. The pillar to which the chordæ tendineæ from the right half of the aortic leaflet of the mitral valve were attached was ruptured close to the point of division. The fragment attached to the valve was yellowish-white, and the endocardium over it opaque. The torn end was irregularly conical, and covered with firmly adherent clot. In the centre was muscle still recognisable surrounded by a yellow opaque ring. The endocardium was thickened below the aortic valve and over some columnæ carneæ, and there were many small endocardial hæmorrhages. The myocardium was greyish-red and its muscular fibres were hypertrophied. In the aorta was a large, oval, corrugated plaque involving the left posterior and anterior cusps. The anterior half of the left posterior cusp was entirely destroyed and the anterior cusp was eroded. Microscopic examination showed a large area of coagulative necrosis in the stump of the ruptured muscle, around which leucocytes had accumulated. Just beyond the leucocytes the muscle fibres had shrunken almost to threads and their striations and nuclei had disappeared. Next to these was a zone of fibres containing droplets of fat. The muscle fibres elsewhere were hypertrophied and the connective tissue was increased. In Levaditi preparations spirochætes were found just beyond the necrotic area. In 1911, Wankel, a German writer, reported a case of ruptured papillary muscle, and in the literature could find only four other cases. In the same year Dr. J. H. Teacher reported a case. In all the rupture was in the left ventricle. In four there was sclerosis of the coronary arteries, and in two thrombosis. In the present and in one recorded case these arteries were normal. In none of the cases was there any reference to syphilis, but in one aneurysm of the aorta was present.

ARMISTICE SUNDAY.

WE are informed by the executive officer of the Joint Council of the British Red Cross and Order of St. John, that the heads of the churches have agreed to recommend that collections should be made in aid of the work of the Council next Armistice Sunday, Nov. 13th. Similar steps have been taken throughout the Empire, so that in all parts of the world worshippers will join in one common act on the same day. In America this has been already arranged. The appeal has met with the hearty approval of the Archbishops of Canterbury, York, and Wales, and the Primate of All Ireland. The Cardinal Archbishop of Westminster has kindly promised to place the matter before his Bishops at their annual meeting in April. The heads of all the Free Churches have signed the memorandum, as [illegible] the Chaplain of the Fleet, and the Chaplain [illegible] the Forces. Where Nov. 13th has, by virtue [illegible] old custom, been reserved for a particular cha[illegible] other convenient date can be selected in the [illegible] that particular church.

A DISAPPOINTING NECESSITY.

A CIRCULAR addressed by the Ministry of Health [illegible] local authorities calls their attention to an [illegible]ment made in the House of Commons in December [illegible] the Chancellor of the Exchequer to the effect that [illegible] spending departments must practise rigid economy, and in particular must hold in abeyance schemes involving expenditure not yet in operation. The circular, applying the principle thus enunciated to the matters within the scope of the authority of the Ministry, recognises the difficulty of economy where the public health is concerned, but states in equally plain terms that the need for lightening the burdens on the community is imperative. The limits there were also no clinical signs of active disease, and the prognosis, as judged by the clinical evidence, was good. In some afebrile cases the normal stability of the blood was much impaired, and the opinion was formed that this test was a much more reliable index to the degree of activity of the disease than the patient's temperature. The rate of sedimentation was invariably increased by fever, particularly when this was due to tuberculosis; and it was noted that a febrile period was often preceded by an increased rate of sedimentation. This test is, however, certainly not specific; in addition to pregnancy and acute infectious diseases, Bright's disease, syphilis, certain forms of "rheumatism," diseases of the blood, and other conditions may greatly hasten the rate of sedimentation. The test would, therefore, seem to be of less value in diagnosis than in determining the degree of activity of tuberculosis and its prognosis.

FIFTIETH ANNUAL MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE fiftieth annual meeting of the American Public Health Association will be held in New York City in November next. The date which is tentatively announced is Nov. 14th–18th. It is especially interesting to ourselves to note that Dr. Stephen Smith, the founder and first President of the Association, who is now entering his ninety-ninth year, is expected to celebrate his approaching centennial, together with the semi-centennial of the Association. Dr. Smith was for many years one of our correspondents in America. The first organisation meeting of the Association was held in New York City on April 18th, 1872, and that is one of the reasons for selecting the same place for the celebration of the semi-centennial. Other considerations are the convenience to foreign representatives and to Dr. Smith, who lives in New York City. Moreover, a plan will then be feasible to conduct demonstrations of public health methods in the laboratories, executive offices, garbage disposal plants, and similar centres of public health interest, where New York City is often a model of administration. It is expected to present in connexion with the celebration a review of the progress of the various branches of public health within the last 50 years. The sectional programmes will include Public Health Administration, Vital Statistics, Laboratory, Food and Drugs, Sociology, Sanitary Engineering, Industrial Hygiene, and Child Hygiene.

CARCINOMA OF THE STOMACH IN A BOY.

Dr. D. A. Laird,[1] of Edinburgh, records the case of a boy, aged 15, with an unimportant hereditary and personal history, who was admitted to hospital for pain in the chest and back of a fortnight's duration, with occasional vomiting. On admission a small, hard, epigastric swelling was found just medial to the left costal margin. There was no tenderness, but a dull pain was complained of over the swelling, radiating to the left scapula. The liver was enlarged and tender. On examination of the blood leucocytosis was found. Both test-meal and vomit showed an absence of free hydrochloric acid. Nothing was found on X ray examination. Seventeen days after admission to hospital laparotomy was performed by Professor Alexis Thomson, who found an inoperable tumour of the lesser curvature of the stomach, with secondary nodules in the liver. Glands were excised from the mesentery for examination and the abdomen was closed. The operation was followed by temporary improvement, but death took place four weeks later, only two months after the onset of the first symptoms. The tumour, which on microscopical examination proved to be a columnar-celled carcinoma, was found at the autopsy to involve the whole of the lesser curvature of the stomach, and the entire posterior wall medial to the cardiac orifice as far as the greater curvature. Perforation of the stomach had occurred shortly before death, as the peritoneal cavity showed gastric contents but no signs of inflammatory reaction. Metastases were found in the liver, pancreas, diaphragm, and the gastric, pyloric, aortic, and mediastinal lymphatic glands. Commenting on the case, Dr. Laird draws attention to the sex of the patient, showing that the great majority of recorded cases of carcinoma of the stomach under 30 have occurred in males, though it may be noted that a case under Sir Norman Moore was in a girl aged 13. Other noticeable features in the present case are the rapid course characteristic of the disease in young subjects, the temporary improvement after laparotomy, which is not infrequent in inoperable carcinomata, and the rare metastatic involvement of the diaphragm.

EXPENSIVE ECONOMY.

THE intention of the London County Council to withdraw its annual grant to the Physiological Laboratory of the University of London, and the consequent decision of the Senate to close the laboratory "failing the assurance of adequate support before the end of March, 1921," threaten a disaster, the extent of which our readers will realise. The laboratory is the only institution in the United Kingdom where the requirements of elementary teaching do not to some extent interfere with the development of research work, and the prospect of deprivation of the facilities for original investigation, which have proved valuable to many workers in physiology, has occasioned strong protest. The Senate have given as a second reason for their resolve, the fact that more space is required for general university purposes, while the London County Council is presumably expecting shortly to have to contribute largely to the establishment of the University on a new site. But whatever the future demand upon space, it is surely worth while to leave the laboratory in situ for what can only be a comparatively short period of time; and the grant of £500 a year now made by the Council does not seem large in view of the expense of the removal of the University already contemplated, and is very small in proportion to the scientific value of the work done. It is to be hoped that the Council will reconsider its decision, and that the Senate, if they cannot see their way to let the laboratory remain in its present quarters, will, at any rate, take steps to house it elsewhere. At a recent meeting of the Medical Faculty of the University resolutions were passed urging the continuance of the work, preferably at the Imperial Institute, and suggesting that, failing the support of the Council, the Senate should allow a sum of £1300 for the triennium ending in August, 1924, even if a portion of that sum has to be taken from the reserve fund of the University. The reserve fund is reported to stand at a considerable figure; but if assistance from this quarter should remain lacking it is almost impossible to believe that some private individual or corporate body will not come forward with the means necessary to ward off what would be a deserved reproach to public intelligence.

CZECHO-SLOVAK MEDICAL COMMISSION.

ON Feb. 18th, at the Czecho-Slovak Legation, the members of the Commission gave to representatives of the press their impressions of a visit to this country, which terminated officially on Feb. 24th. The members of the Commission, who were officials of the Czecho-Slovakian Ministry of Public Health and Physical Education, said they had studied the English and American systems rather from the point of view of public hygiene and sanitation than from that of medicine. Comparing the English and American services they expressed the opinion that the former, with its combination of central and local control, was more suited for adaptation to the needs of their own country. They were accustomed to State organisation—the old Austrian system had been completely centralised and very uneconomical—and nothing in England had impressed them more than the voluntary hospitals. They had obtained much valuable information in matters of school hygiene and child welfare generally, including pre-natal care and milk control; the milk shortage in Czecho-Slovakia was at present a source of great difficulty. A movement was already on foot in that country to group districts together for the more comprehensive treatment of tuberculosis and venereal diseases; in the matter of the education of medical officers of health and lay health visitors they hoped to follow the English example. Their public health officials were only allowed to enter the service after two years' ordinary practice; hitherto, moreover. no body comparable to the English health visitors had been organised. Water-supply and housing had also attracted the special attention of the Commission. With regard to physical education in Czecho-Slovakia, it was remarked that a law would shortly be enacted making compulsory a system of training for men up to the age of 21—i.e., up to the beginning of the period of military service. All townships, &c., would be required to provide and maintain space and apparatus for the working of this national scheme. The compulsion was not extended to girls, but the "Sokol" Athletic Association, with branches all over the country, was awakening widespread interest in the physical development of both sexes. Questioned as to the expense of the projected reorganisation of public health services in Czecho-Slovakia, Dr. Karel Driml, who acted as interpreter, explained that the State would bear the entire cost, and that the impoverished condition of the country would make it necessary to move slowly. In conclusion, members of the Commission expressed the gratification afforded them by the cordiality of their reception in this country, and whilst regretting the short duration of their visit and the resultant limitation of their movements, they hoped that the contact thus established with English medical and public health institutions would be maintained with mutual advantage. They wished particularly to mention with gratitude the name of Dr. J. A. Glover, of the Ministry of Health, who had acted as their guide throughout the visit and had given them every possible assistance.

---

[1] Edinburgh Medical Journal, February, 1921.

RUPTURE OF SYPHILITIC PAPILLARY MUSCLE.

A CASE of a very rare accident—rupture of a papillary muscle of the heart—has recently been reported by E. D. Spalding and W. C. Von Glahn.[1] A coloured labourer, aged 31 years, was admitted to the City Hospital, Baltimore, on March 23rd, 1920. There was a history of a venereal sore in 1905 and of a miscarriage of his wife. Fifteen months before admission he had an attack of hoarseness for three weeks, after which he suffered from dyspnœa and nocturnal cough with bloody sputum. This subsided spontaneously, but returned more severely a year later, when he was admitted to the University of Maryland Hospital on Jan. 5th, 1920. The apex beat was in the sixth interspace 14 cm. to the left, where an indefinite presystolic thrill was felt. There was a diffuse præcordial heave. At the apex the sounds were replaced by a blowing systolic and short diastolic murmur. At the base and down the sternum a short diastolic murmur replaced the aortic second sound. The second pulmonic sound was accentuated. There was slight dullness at the base of the right lung behind, and the liver extended three finger-breadths below the ribs. Blood examination showed slight secondary anæmia and a positive Wassermann reaction. The X rays revealed an enlarged heart and aorta and clouding at the base of the right lung. Compensation was gradually restored, and he was discharged on Feb. 27th. He steadily went down hill, and after a month was admitted to the City Hospital. He was œdematous and dyspnœic. The pulse was rather rapid and collapsing but regular, and of fair quality. He did not appear to be in a bad condition, and was given a bath in the ward. Immediately afterwards he complained of feeling ill. He was cyanotic, sweating, and very dyspnœic with rapid, thin, and weak pulse. He was wheeled to his bed, and three minutes later was frothing at the mouth and nose. The heart was found greatly dilated, chiefly to the left. Venesection was immediately done, strophanthin administered intravenously, and morphine and atropine subcutaneously. The pulse became stronger, but the respirations were slow and very laboured, with tracheal rhonchi. He was turned on his face and artificial respiration performed, but he soon died. The diagnosis was aortic and acute myocardial insufficiency due to syphilis. The necropsy showed a greatly hypertrophied heart, chronic passive congestion of the viscera, and œdema of the lungs. The cavity of the left ventricle was much enlarged, measuring 12 cm. from mitral ring to apex. The posterior papillary muscle was Y-shaped, being divided into two pillars. The pillar to which the chordæ tendineæ from the right half of the aortic leaflet of the mitral valve were attached was ruptured close to the point of division. The fragment attached to the valve was yellowish-white, and the endocardium over it opaque. The torn end was irregularly conical, and covered with firmly adherent clot. In the centre was muscle still recognisable surrounded by a yellow opaque ring. The endocardium was thickened below the aortic valve and over some columnæ carneæ, and there were many small endocardial hæmorrhages. The myocardium was greyish-red and its muscular fibres were hypertrophied. In the aorta was a large, oval, corrugated plaque involving the left posterior and anterior cusps. The anterior half of the left posterior cusp was entirely destroyed and the anterior cusp was eroded. Microscopic examination showed a large area of coagulative necrosis in the stump of the ruptured muscle, around which leucocytes had accumulated. Just beyond the leucocytes the muscle fibres had shrunken almost to threads and their striations and nuclei had disappeared. Next to these was a zone of fibres containing droplets of fat. The muscle fibres elsewhere were hypertrophied and the connective tissue was increased. In Levaditi preparations spirochætes were found just beyond the necrotic area. In 1911, Wankel, a German writer, reported a case of ruptured papillary muscle, and in the literature could find only four other cases. In the same year Dr. J. H. Teacher reported a case. In all the rupture was in the left ventricle. In four there was sclerosis of the coronary arteries, and in two thrombosis. In the present and in one recorded case these arteries were normal. In none of the cases was there any reference to syphilis, but in one aneurysm of the aorta was present.

ARMISTICE SUNDAY.

WE are informed by the executive officer of the Joint Council of the British Red Cross and Order of St. John, that the heads of the churches have agreed to recommend that collections should be made in aid of the work of the Council next Armistice Sunday, Nov. 13th. Similar steps have been taken throughout the Empire, so that in all parts of the world worshippers will join in one common act on the same day. In America this has been already arranged. The appeal has met with the hearty approval of the Archbishops of Canterbury, York, and Wales, and the Primate of All Ireland. The Cardinal Archbishop of Westminster has kindly promised to place the matter before his Bishops at their annual meeting in April. The heads of all the Free Churches have signed the memorandum, as also has the Chaplain of the Fleet, and the Chaplain General of the Forces. Where Nov. 13th has, by virtue of some old custom, been reserved for a particular charity, some other convenient date can be selected in the case of that particular church.

A DISAPPOINTING NECESSITY.

A CIRCULAR addressed by the Ministry of Health to local authorities calls their attention to an announcement made in the House of Commons in December by the Chancellor of the Exchequer to the effect that all spending departments must practise rigid economy, and in particular must hold in abeyance schemes involving expenditure not yet in operation. The circular, applying the principle thus enunciated to the matters within the scope of the authority of the Ministry, recognises the difficulty of economy where the public health is concerned, but states in equally plain terms that the need for lightening the burdens on the community is imperative. The policy, it declares, must be to restrict expenditure to what is immediately necessary in the interest of the public health, to utilise existing premises and staffs to the fullest advantage, to secure full value for every pound spent, and to refrain in general from capital expenditure. In addition to the practice of economy of the ratepayers' money, private help and benevolence must be called in aid as much as possible in the promotion of useful auxiliary services. Services particularly mentioned in the circular are those concerned with the treatment of tuberculosis and of venereal disease and with the welfare of the blind. With regard to these, as to other matters, it is insisted that there should be no capital expenditure except where work has been begun and cannot be abandoned or modified. It is particularly against new building schemes that the circular is directed. The necessity for general economy of expenditure, in view of the huge burden now imposed upon rateable property, cannot be denied. It is disappointing that a new Ministry having high hopes of great and good work before it should have to hold its hand and to restrain the hands of others, where the promotion of the public health is involved, but it must be recognised that in thus insisting on economy it has done no more than the situation demands.

---

[1] Johns Hopkins Hospital Bulletin, January, 1921.

CHILD WELFARE IN AUSTRIA.

IN the early winter of 1919 there were in Vienna 36 infant welfare centres, at which 20,000 children were attending. Of these centres, eight were in the hands of the municipal authorities, while four independent organisations were responsible for the remainder. Many of these dealt with the first year of life only, but the work of the municipal institutions was broader, including antenatal consultations and the care of the child up to the age of 18. Most of the centres were well organised with up-to-date appliances and competent medical treatment; but all were handicapped by the scarcity of such elemental necessaries as milk, soap, linen, and paper. From 80 to 90 per cent. of the attending one-to-fives were found to be rachitic or tuberculous and stationary in weight; and when in November, 1919, the Society of Friends' Relief Mission was able to arrange for small regular supplies of food to certain constant attenders of centres the rise in weight of the children was frequently extraordinary. Depôts were opened where mothers of such children could obtain a ration for them on production of a card signed by the doctor of a welfare centre, the charge made being estimated with regard to the father's earning capacity, some 15 per cent. of the rations being supplied free. It is hardly surprising that the number of children eligible for these rations very soon became too great to deal with, and the Vienna Board of Health then combined all infant welfare organisations into one body, the Hauptausschuss für gesundheitliche Jugendfürsorge. Existing centres were extended and reorganised, with the result that it was possible to open 34 new centres, to examine all the children in the city under six years of age, and to keep those who required it under supervision. Equipment was still scanty; children were weighed on luggage-scales and examined on tables for which, as a rule, neither cloth nor paper covering was obtainable. A timely gift of soap from the American Red Cross enabled medical officers to wash their hands. How keenly this work among the children appeals to local workers is evident from the fact that during a recent collection for the children in Vienna doctors and nurses contributed one-tenth of their monthly salaries; at what sacrifice may be seen from a study of our Vienna Correspondent's recent letters. Between June and October of last year 85,000 children were examined, 54,000 of whom were receiving supplementary fortnightly rations, and it was possible to note some improvement on the conditions of 1919; although only 10 per cent. were normal in weight, no more than 56·1 per cent. showed signs of actual disease. It is an extraordinary fact, and one of great interest to the study of scientific dietetics, how small has been the increment necessary to change a down-grade or stationary child into an up-grade one. Fortunately, much study is being given in Vienna to these new and intimate problems of national nutrition. Dr. Harriette Chick and Dr. Elsie Dalyell, on behalf of the Lister Institute, are still working in Vienna hospitals at the problem of vitamines and the most effective way of utilising them on a minimum caloric diet. We publish this week a valuable study of the food-supply and state of nutrition of a representative sample of the Viennese working classes by Miss M. R. Gribbon and Miss M. Ferguson, the two investigators using methods which under Professor Noel Paton, of Glasgow, have already thrown light on the ætiology of rickets nearer home. In the remainder of German-speaking Austria a system of infant welfare centres has been established, controlled by a central body, the Landesjugendamt. The conditions, especially in the small industrial towns, are at present actually worse than those in Vienna, for food-supplies are inadequate and assistance is not so widely available. There is ample scope within the borders of the old Hapsburg dynasty not only for abundant charity but also for the discerning brains which shall apply this charity to the best results.

A HANDICAP REDUCED.

Dr. Monod demonstrated the retarded kinema on Feb. 23rd to a hall filled to capacity. Moreover, even those among his audience who normally take but little interest in medical politics listened with sympathy to his ideals of a closer bond between the profession in England and France, and with keen attention to his tentative plans for its promotion. The subject was not devoid of difficulties, but so tactful was his approach and so reasonable his appeal that the success of Dr. Monod's mission is assured. Many arrived quite ready to cement cordial professional relations with a country showing such a neighbourly interest in the reduction of their golf handicaps, and left convinced of other even more important advantages to be gained from a closer fellowship with their colleagues in France. The actual show was novel to many of those present. The slowed pictures of athletes putting the weight, throwing the discus, and jumping with and without the aid of a pole were miracles of effortless grace. No sign of sudden stress was apparent at any one moment, though an increase or relaxation of muscular tension might be detected on closer study. Dr. Monod made the interesting claim for his compatriot, the physiologist Marey, of having invented the apparatus for taking a rapid series of photographs of life in motion. But for the perforations along the edge of the film, he left little for subsequent ingenuity. The cardiac film was, as Dr. Monod said, more an indication of the possibilities of this method in physiological research than a contribution to our knowledge of heart movements; the pathology of the heart-lung preparation, said to be in a state of auricular fibrillation, was not very clear. An exposition of the golf swing, however, gave great satisfaction, but it would be necessary to administer a "repeat" of the mixture of several movements many times before their analysis could be used to cure individual faults; unfortunately, the films were shown to the sufferers only once. But if Dr. Monod failed to effect a general reduction of golf handicaps, he achieved a big step towards the reduction, if not the removal, at least of that handicap to universal medical fellowship which depends only on insular prejudice.

WE regret to announce the death on March 1st of Sir Felix Semon in his seventy-second year.

A DISCUSSION upon the Eradication of Tuberculosis in Men and Animals will be held in the Robert Barnes Hall of the Royal Society of Medicine, 1, Wimpole-street, London, W., on Monday, March 14th, at 5.30 P.M. The discussion will be opened by Sir John McFadyean, who will be followed by Sir Clifford Allbutt, Sir G. Sims Woodhead, Dr. Arthur Latham, Professor Hobday, Dr. A. C. Inman, Mr. Cyril Nitch, Dr. H. Sutherland, and others. The chair will be taken by Sir John Bland-Sutton.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

A Challenge to Professional Secrecy.

THE text of the Order[1] issued in various parts of Ireland by the competent military authority, and served on the secretaries of the general hospitals and the medical officers of certain workhouse and district hospitals, has naturally caused much perturbation in the minds of the medical men affected thereby, and it opens a professional question of more than local interest. The demand made by a legally constituted authority that doctors are to act as informants in regard to their own patients is, as far as we know, unprecedented in these countries. It is stated by Dr. George Sigerson, in an interview reported in a Dublin paper, that a similar demand was made on the Paris hospitals in the time of Napoleon III., but the hospitals refused to obey. There is no point of ethics to which the medical profession has clung more tenaciously than its obligation to secrecy as regards personal knowledge gained in professional work. From Hippocrates down to the present day professional confidences have been regarded as inviolate.

The latest collective pronouncement regarding secrecy made on behalf of the profession is that of the Representative Meeting of the British Medical Association held last June at Cambridge. It is in the following terms:—

> That having further considered the question of professional secrecy viewed from the standpoint of the medical profession and with special regard to venereal diseases, the Representative Body reiterates the opinion that a medical practitioner should not, without his patient's consent, voluntarily disclose information which he has obtained from such patient in the exercise of his professional duties.

Though the meeting was specially considering the problems arising out of the State-provided treatment of venereal diseases, the proposition is general. How far a medical man in obeying the military Order in Ireland would be acting voluntarily or under compulsion it is difficult to say, but it is clear that in giving information regarding his patients in obedience to a general order he would be going much further than if he were merely to answer specific questions when produced as a witness in court. The duty of a medical man who, from information gained professionally, suspects that a crime has been committed is by no means clear. Dixon Mann[2] says:—

> "It is not part of his [the practitioner's] duty to act as a detective and give information to the police whenever he comes across crime. Yet at the same time he must use reasonable discretion, and in a serious case he may be justified in subordinating the immediate personal obligation to public duty."

He further quotes from Mr. Justice Hawkins:—

> "When it was said that there was a general rule existing in the medical profession, that whensoever they saw, in the course of their medical attendance, that a crime had been committed, or was about to be committed, they were in all cases to go off to the Public Prosecutor, he was bound to say that it was not a rule which met with his approbation, and he hoped it would not meet with the approbation of anyone else. There might be cases where it was the obvious duty of a medical man to speak out."

What is more pertinent, perhaps, in the present state of Ireland is that the Order is not likely to prove effective as regards its object, while it may have the undesirable result of estranging the medical profession as a whole from those whose sole duty in Ireland is to restore law and order. It is understood that the Council of the Royal College of Surgeons in Ireland has, after serious consideration, decided to make representations on the subject to the military authorities. We may hope that as a result of such representations the authorities may decide to withdraw, or if that is impolitic, to ignore the Order.

Trial of a Doctor's Wife.

It is announced that Mrs. Ryan, of Wexford, wife of Dr. James Ryan, M.P. for South Wexford, has been fined £50 by a military court in Waterford for refusing to post in one of the windows of her house a notice proclaiming martial law. In default of the payment of the fine within seven days a distress was to be levied on her goods, and in default of distress she was ordered three months' imprisonment. Dr. James Ryan has been under arrest for some weeks past without being brought to trial. He is stated to have been carried as "a hostage" in lorries patrolling disturbed areas.

Death of Sir Charles Cameron.

The death of Sir Charles Cameron, the veteran medical officer of health of Dublin, occurred last Sunday, in his ninety-first year, after a prolonged illness. The only surviving son of Captain Ewen Cameron, of Lochaber, and educated at Dublin and Guernsey, he was already public analyst in the capital before taking medical qualifications at the Coombe Hospital, Dublin, when he was 38 years old. A few years later he became F.R.C.S. Irel. and D.P.H. Camb., thus equipping himself on many sides for the position of adviser to the public health department of the Dublin Corporation, a position which he held for half a century. Over and above his onerous official duties Cameron found time to preside for some years over the Royal College of Surgeons of Ireland, in which he occupied the chairs of hygiene and chemistry. He was Harben gold medallist in 1902. In 1885 he received the signal honour of knighthood in recognition of his services to public health, being the first health officer to be thus distinguished. Professional honours of all kinds naturally fell to his share. Sir Charles Cameron was a prolific writer with a flowing pen and lucid style. His "Manual of Hygiene and Compendium of Sanitary Laws" found readers of all kinds, and his "History of the Royal College of Surgeons in Ireland" has taken its place in the archives of medical history.

Ulster Medical Society: Annual Dinner.

The annual dinner of the society was held in the Medical Institute, Belfast, on Feb. 17th, when Dr. Houston, the President, occupied the chair; the company numbered about 70. Among the guests were Sir Almroth Wright, F.R.S.; Judge Matheson, Recorder of Belfast; the High Sheriff, Councillor W. G. Turner; Mr. S. G. Crymble, president of the Northern Law Society; and Dr. Alexander Fleming. After dinner the President gave the toast of "The King," which was received with enthusiasm. Professor J. A. Lindsay proposed the toast of "The Belfast Corporation," which was responded to by the High Sheriff in the absence of the Lord Mayor, who had been called to London on official business. The President gave the toast of "Our Guests," and spoke of Sir Almroth Wright's important contributions to medical science and of his cordial relations with those members of the society who had visited his laboratory at St. Mary's Hospital. Sir Almroth Wright, in responding, emphasised the importance of experiment in the advance of scientific truth, and expressed his conviction of the fallaciousness of too much reliance upon experience. Dr. Fleming also responded. Dr. J. S. Morrow gave the toast of "The Legal Profession" in an amusing speech. Judge Matheson, in responding, paid a high tribute to the beneficent work and the high ethical standards of the medical profession. Mr. Crymble also responded. Dr. J. E. MacIlwaine gave the toast of "The President." Dr. Houston made a suitable response, and concluded by proposing the toast of the acting secretary, Dr. R. Marshall, to whom the success of the evening was mainly due. Dr. Marshall, in acknowledging the toast, expressed the pleasure which the members of the society felt at the convalescence from his long illness of the secretary, Dr. W. W. D. Thomson. On the following afternoon Sir Almroth Wright addressed the society on the subject of Acidæmia. There was a crowded attendance and the address was heard with much interest and pleasure.

Belfast Maternity Hospital.

The annual meeting of this institution was held on Feb. 24th, Mr. Herbert Ewart, chairman of the board of governors, in the chair. The annual report showed a large increase in the volume of work during the past year, both in the hospital and the district work carried on in connexion with the institution. During the year 831 patients were treated, 517 children were born, 31 were stillborn, and 13 died. In the district work 4774 visits were paid. The maternal death-rate was 1·34 per cent. The report made sympathetic reference to the resignation of Dr. Brice Smyth after a connexion with the hospital for the long period of 50 years, and to the death of Sir John Byers. Professor C. G. Lowry and Mr. T. S. S. Holmes, F.R.C.S., had joined the staff. Twenty-one nurses had entered for and passed the C.M.B. examination. The financial report showed a small deficit, £120, on the year's working. The endowment fund had been considerably augmented. In seconding the adoption of the report, Professor Lindsay mentioned that in the ensuing year the hospital would undertake work in connexion with the maternity and child welfare movement. He also dwelt upon the *necessity for larger accommodation for maternity* work in Belfast. Dr. H. D. Osborne was elected a governor in succession to Dr. Brice Smyth, resigned.

Central Midwives Board for Ireland.

A meeting was held at the office of the Minister of Health, St. Stephen's Green, Dublin, on Feb. 24th, with Sir Edward Coey Bigger in the chair. The secretary reported that at the examination held in Dublin, Belfast, and Cork simultaneously on Feb. 8th and 9th 63 candidates presented themselves, of whom 61 passed and were granted certificates. The total number on the Midwives Roll of Ireland is now 2902. At a special meeting of the Board subsequently held the name of one of the midwives was removed from the Roll.

Feb. 28th.

TUBERCULOSIS.

When is a War Pensioner Tuberculous?

IN 1918 Dr. Büttner-Wobst published a paper in which he made out that from 60 to 80 per cent. of the cases admitted to sanatoriums in Germany were not really tuberculous. His paper roused a good deal of criticism, and last year Dr. M. Landolt published a lengthy statistical analysis of sanatorium material, showing that only in about 6 per cent. could the original diagnosis of tuberculosis be regarded as mistaken. With these discrepant opinions for a background, it is well worth scrutinising a remarkable statement made by the London Insurance Committee. It appears that arrangements were recently made with the Brompton and City of London Chest Hospitals for the admission of 158 cases for observation. They included 73 ex-Service cases in which the diagnosis of tuberculosis had been accepted by the Ministry of Pensions and queried by tuberculosis officers. There were 37 cases regarded as tuberculous by tuberculosis officers and 48 recommended for diagnostic observation by tuberculosis officers. Of the total of 158 cases, 124, or more than 78 per cent., were considered by the hospitals mentioned as "not suffering from tuberculosis." In ten other cases the disease was regarded as arrested. Thus only 15 per cent. of the 158 cases were recommended for treatment. At first sight these figures are certainly disconcerting; they suggest incompetence to the unitiated, ignorant of the usual difficulties in the early diagnosis of tuberculosis and the special difficulties connected with a pension. These are indeed great, and one of the thoughts in the mind of a conscientious tuberculosis officer is this: I cannot be sure whether this man is tuberculous or not. If I give him the benefit of the doubt he will enjoy skilled treatment, with periodic "boards" at which a mistake, if committed, can be rectified. But if I label him non-tuberculous bitter experience has taught me that, in the event of his proving tuberculous after all, the task of securing him a tuberculosis pension will be most tedious, exasperating, and often hopeless. By their mistaken parsimony in such cases the pensions authorities have defeated their own object, and have driven tuberculosis officers to take a course which, under the circumstances, is perfectly justifiable. The remedy for this state of affairs is obvious. Another remedy which this report clearly indicates is the provision of every tuberculosis officer with a certain number of observation beds. It may be possible to diagnose advanced cases in an overcrowded dispensary, but it is absolutely impossible to decide that a case is definitely non-tuberculous. Even in a hospital, and with a case under observation for several days, the unequivocal exclusion of tuberculosis from the possible diagnoses calls not only for great skill and experience, but also in some cases for a remarkable degree of assurance. It may be noted in this connexion that already two cases reported by a hospital as not being tuberculous have subsequently shown conclusive evidence of the disease. There can be little doubt that if every first-stage patient who was sputum-positive ten years ago, and who had since kept well, were examined for tuberculosis in a hospital, a goodly proportion would be discharged as non-tuberculous if their previous records were concealed. Yet the aphorism, "Once tuberculous always tuberculous," is undeniably true.

Heredity in Tuberculosis.

In a paper in the *American Review of Tuberculosis* for November, Dr. Raymond Pearl has published some suggestive figures dealing with the problem of infection and heredity in relation to tuberculosis. His observations are the more valuable as they are leavened by a canny recognition of the many pitfalls awaiting the investigator who attempts to discover the comparative importance of heredity and infection. He has investigated 57 family histories, involving more than 5000 blood relatives. In 38 cases the original subject of investigation was tuberculous, and in 19 cases non-tuberculous. Each group could be regarded as a random sample of the working-class population of Baltimore, the only differential factor in the selection being that in the one case the individual with whom a history started was tuberculous, and in the other case not. Five generations were studied with the following striking results. A tuberculous person, it was found, had nearly six times as many tuberculous blood relatives as a non-tuberculous person. In other words, 7 per cent. of the blood relatives of a tuberculous person were themselves tuberculous, whereas this was the case with only 1·2 per cent. for the non-tuberculous. Where there was no immediate tuberculous ancestry (parents and grandparents non-tuberculous) 7·4 per cent. of the offspring were actively tuberculous. Nearly a quarter (22·2 per cent.) of these tuberculous progeny were known to have lived for some time before developing the disease in close contact with cases of active tuberculosis. On the other hand, of the 92·6 per cent. non-tuberculous offspring of non-tuberculous ancestry, only about one-tenth (11·2 per cent.) had been in close contact with an active case. Thus, twice as many of the tuberculous offspring of non-tuberculous ancestry had been in close contact with active tuberculosis, as had been the case with the non-tuberculous offspring of non-tuberculous ancestry. These figures stress the importance of infection. But, as Dr. Pearl points out, when one or both of the parents were actively tuberculous virtually three-fourths of their non-tuberculous offspring had been in just as close contact with active, open cases as their brothers and sisters who developed the disease. Dr. Pearl's figures show that familial contact with active, open cases is undoubtedly a factor in determining the incidence-rate of clinically active tuberculosis, but he thinks it equally obvious that such contact does certainly not account for the whole, and it probably accounts only for a small part, of the increase in the incidence of the disease occurring as the amount of tuberculosis in the immediate direct ancestry increases.

The Farming Out of Sanatorium Patients.

In his report for the year ending March 31st, 1920, Dr. C. Rolleston, tuberculosis officer to the Soke of Peterborough, has some candid remarks to make on the system, adopted by certain local bodies, of farming out their sanatorium cases. The disadvantages of this arrangement are illustrated by the case of a patient of over 50 who acquired tuberculosis in the army. Farmed out by the War Pensions Committee in a distant sanatorium he was suddenly discharged without a word of warning to the committee or their medical officer. His home was a common lodging-house, where his opportunities for spreading the disease would be unrivalled. Yet no opportunity was given for arranging further institutional treatment prior to his discharge. Dr. Rolleston points out that the distance of all sanatoriums from Peterborough undoubtedly deters many patients from staying for the necessary period in a sanatorium. As his figures show, the Soke of Peterborough could keep a 50-bed institution full of its own patients; and were such an institution provided in the county area friends and relatives could visit patients, who would thus be encouraged to submit to the tedium of a long stay. Dr. Rolleston is to be congratulated on bringing into prominence one of the most important causes of sanatorium unrest in this country. His recognition of the importance of rest is summed up in the advice he gives to the wives of his patients: "Take away his trousers; his lungs will take care of themselves."

Surgical Tuberculosis in Switzerland.

At a recent meeting of the Swiss League against Tuberculosis special attention was drawn to the needs of those suffering from surgical tuberculosis. Their number in the whole country is reckoned as being about 15,000. Statistics at Basle have shown that among 100 such cases only 3 belong to the wealthy classes, 28 to the middle classes, and 69 to the poor. Hence the urgent need of some public help. Both Dr. Rollier, of Leysin, and Professor de Quervain, of Berne, pointed out that special care should be taken to secure for these cases treatment in an Alpine sanatorium. Dr. Rollier was able to show from his experiences of twenty years what the "cure hélio-Alpine," as he calls it, can achieve. All cases of surgical tuberculosis, except certain forms of fungous synovitis of the knee-joint or of genito-urinary affection, benefit greatly by it. It is often said that this holds good only for children, but at Leysin adults have always been in a majority, and their prognosis is not less favourable, nor is the duration of their treatment, longer than that of children. Dr. Rollier produced the following statistics of 2167 cases treated since the beginning of the war and controlled by skiagrams: cured, 1746; ameliorated, 242; no change, 147; worse, 32. With the hélio-Alpine treatment Dr. Rollier has combined a treatment of work. He founded at Leysin work and agricultural colonies which met with great success; up to the present the special sanatorium at Leysin has been the only institution in the country for the treatment of surgical tuberculosis of the poorer classes. Professor de Quervain urged that this example should be followed throughout the country. There are two solutions, the foundation of special sanatoriums and the formation of special wards in the ordinary sanatoriums for pulmonary cases. Such wards, however, require a staff of surgical specialists, as the treatment of surgical tuberculosis combining orthopædic, operative, and conservative measures with X ray cure demands, no less than the pulmonary form, a special knowledge. In this connexion the universities of Geneva, Lausanne, and Neuchâtel have launched a notable scheme—namely, the foundation of a sanatorium at Leysin specially for teachers and students of those universities suffering from tuberculosis of a curable nature. To realise this scheme a large sum of money is needed. The idea has been taken up with great enthusiasm by the universities, and a campaign has been opened in its favour. A Bill for measures against tuberculosis will soon be brought before the Federal Chambers. Hitherto the campaign has been carried on entirely by private persons, cantons, and municipalities, with varied vigour in different parts of the country. The new Bill, far from abolishing private initiative, will centralise and concentrate efforts already in operation. It also provides compulsory notification of all cases.

PAYING PATIENTS IN POOR-LAW HOSPITALS.—Reference has already been made in THE LANCET to the scheme of the Manchester board of guardians now in operation in their hospitals at Withington and Crumpsall, whereby people who cannot pay the fees of private nursing homes are admitted to all the benefits of hospital treatment, attendance, and keep for 3 guineas per week. Patients suffering from acute but not infectious or contagious diseases are admitted, and the scheme has been in operation since Feb. 1st. In view of the important principles involved, the Ministry of Health has asked for a full statement of the exact nature of the proposals and what, if any, steps have been taken towards bringing them into operation. The board's unanimous resolution, in reply, took the form of an explanation of the guardians' scheme, pointing out that their scheme is similar to those adopted in many other unions. The guardians add that the institutions have relieved many sick persons of the necessity of waiting many months before obtaining admission to a voluntary hospital, and they trust that the Ministry of Health will give them every assistance in the carrying out of their scheme.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

CITY OF SHEFFIELD.

Dr. H. Scurfield has issued his report for 1920. Though a short document, it contains many points of interest. The difficulty of making an accurate estimate of the population for the years of the war and since the armistice is dealt with. The population was depleted by the men joining the Services, but there was also a great influx of munitions workers. For the birth-rate the population is estimated at 493,839; for the death-rate at 492,570. There has been a great jump in the birth-rate. The number of births registered was 13,186, being 2770 more than in the previous year. This gives a birth-rate of 26·7 and is the highest recorded since 1914, when it was 27·3. The war decline continued till the first quarter of 1919, the quarterly birth-rates for 1919 being successively 16·2, 16·8, 19·6, and 26·6, and for 1920 28·8, 26·9, 26·4, and 24·6. There were 6660 deaths registered, being 41 less than in the previous year, and the death-rate is estimated to be 13·5, being the lowest ever recorded for the city.

For the first time on record not a single death has been attributed to *enteric fever*, and it is mentioned that since 1914, in contrast with previous years, there has been no autumnal increase in the prevalence of this disease.

The steady decline in the death-rate from *tuberculosis* which took place during the first years of the century had a set-back during the war. The increase during the war was greater among females than among males, no doubt owing to the increased amount of female factory labour. Since the armistice this increase in the tuberculosis death-rate has disappeared with remarkable rapidity, rendered all the more remarkable by the fact that the improvement has taken place in spite of the bad housing conditions and overcrowding which are referred to in another part of the report. There is an increase in the number of new cases of sickness from tuberculosis of the lungs, but this is attributed to the increase in the war-depleted medical staff of the tuberculosis dispensary, which has enabled the examination of "suspects" and "contacts" to be carried out more thoroughly.

There is an increased number of deaths from *cancer*—namely, 521 for 1920 as compared with an average of 471 for the previous five years. This increase is among the male deaths, which are 254 for 1920 and 209 for the previous quinquennium, the female deaths from cancer during 1920, being 267 as compared with 262 for 1915–19.

The *infant mortality* is 103 per 1000 births as compared with 96 in 1919, which was the lowest ever recorded for Sheffield. Although 103 is Sheffield's second best on record it is shown on page 7 to be 23 in excess of the rate for England and Wales, and one wonders to what extent this is attributable to the bad conditions for infants resulting from the overcrowding. The neo-natal mortality was 38 per 1000 births and has to be compared with 43 for the year 1919. Dr. Scurfield draws attention to a slight recrudescence of influenza which took place during May, 1920, and gives reasons for supposing that Blackburn, Halifax, and Sunderland were similarly affected during the month of April.

The work of the *maternity and child welfare* department goes on increasing. There were 51,456 attendances at the "baby consultations" as compared with 39,316 in the previous year. The pre-natal work is not extensive. Only 112 new cases attended, 47 of whom were recommended by midwives and 48 by the women inspectors.

Dental cases.—Only nine patients were treated by the dentist. It is obvious that the need for attention to the teeth of the expectant and nursing mother is not understood in Sheffield, and that a large amount of propaganda work will have to be done in order to combat the widespread superstition that it is not safe for the mother to have her teeth put right at these times. Few things have been more striking recently than the demonstration of the effect on the nursling's health produced by having the mother's decayed teeth extracted and her mouth "cleaned up."

In spite of overcrowding and want of proper lying-in accommodation for the largely increased number of confinements, the *death-rate from puerperal fever* and other complications of childbirth is lower than in the two previous years. When the triennium 1918–20 is compared with the pre-war triennium an increase in the death-rate per 1000 births from puerperal fever from 1·3 to 1·8 is recorded, while the death-rate from other complications of child-bearing remains the same.

During 1920 302 cases of *ophthalmia neonatorum* were recorded as compared with 219 in 1919. This increase is partly accounted for by the increase in the number of births from 10,146 in 1919 to 13,186 in 1920. During 1920, however, the damage to the eyes was much greater. In 1919 there were no cases of lost eyesight known to have occurred. In 1920 two children were blinded in one eye and one in both eyes. The blind child died subsequently. In addition, there were 20 cases under observation at the end of the year, including some severe ones which are likely to cause further eye-destruction. We believe that ophthalmic surgeons are agreed that these cases should hardly ever occur with proper attention at birth, as in a well-conducted lying-in hospital, and that when they do occur the eyesight should, practically speaking, never be lost if efficient treatment is applied at once. We have, therefore, to face the fact that somewhere about one-third of the inmates of blind institutions are there owing to inefficiently treated ophthalmia neonatorum.

The work of the Sheffield clinics for *venereal diseases* is shown in the following statement:—

	1918.	*1919.*	*1920.*
Total number of persons dealt with ...	1,805	3,215	4,871
Total attendances of out-patients ...	12,846	21,770	28,359
Total number of in-patient days ..	4,345	3,189	2,856

The cost per person dealt with was £3 0*s.* 9*d.* in 1918, £2 5*s.* 4*d.* in 1919, and £1 14*s.* 3*d.* in 1920. The diminished cost per person is due to the fact that it has been found possible to give a greater proportion of the injections of salvarsan substitutes to out-patients.

We are surprised to learn that Sheffield has still as many as 10,800 privies requiring conversion.

Housing question.—With regard to the housing question Dr. Scurfield says:—

> "The unsatisfactory feature of the year's work has been the increase in overcrowding owing to the fact that sufficient houses are not being built to accommodate the natural increase of the population. In this respect Sheffield is in a similar position to the other large towns of the country. It is impossible to condemn houses, however unfit for habitation they may be, and unless there is a very great change it will be years before we can dream of clearing slums and providing open spaces in the congested parts of our great towns."

A statement is given showing the houses built since 1886, and during each month since the armistice, followed by the comment:—

> "It will be noticed that 267 new houses have been provided during the year 1920. During the same period there were 5075 marriages and 6526 more births than deaths."

A truly appalling state of affairs!

The report concludes with tables showing the death-rates, &c., in the various subsections of the city, and a comparison of the Sheffield statistics with those of the 45 largest towns of England and Wales. In the subsections of the city the birth-rate varies from 37 in Park A to 17·25 in Broomhall B; the death-rate from all causes from 21·55 in Sheffield North B to 8·52 in Brightside West B; and the infant mortality from 172 in Sheffield North B to 69 in Brightside West B. The table for the 45 towns shows that there were 17 towns with higher birth-rates than Sheffield, 13 with higher death-rates, and 9 with higher infant mortality rates.

COUNTY OF KENT.

Some interesting problems connected with the administrative control of certain infectious diseases are discussed in Dr. Alfred Greenwood's annual report for the year 1919. On the subject of scarlet fever, allusion is made to "return" cases and extracts on the subject from the reports of the M.O.H.'s of Chislehurst and Ramsgate are given. In the former district an arrangement is apparently in operation by which cases discharged from the isolation hospital are examined at their homes within three days of their return by the medical practitioner who originally notified the case, and he supplies a short report on the subject. This is done with the object of preventing "return" cases. It is unfortunate that no indication of the success or failure of this procedure is given, but perhaps it has not yet been sufficiently long in operation to justify any conclusion on the subject.

Every precaution is taken in Ramsgate by the hospital authorities with the object of reducing the number of "return" cases as much as possible. With this end in view no scarlet fever patient is allowed to leave the hospital until all nasal discharge and all objective signs of complications have ceased for some time; but, in spite of this, it is impossible to prevent the occurrence of "return" cases, as, in the absence of knowledge of the cause of the disease, it is difficult to say definitely when a convalescent patient is in fact non-infectious. In some instances the infection may be quiescent at the time the patient leaves the hospital, yet an infectious nasal discharge or other morbid condition of the nose may develop or recur some time after returning home. It is therefore important, especially in the case of children, that for three weeks after leaving hospital the patient should not sleep in the same bed, or, if possible, in the same room, with children who have not had scarlet fever, and that during this period all articles such as cups, spoons, handkerchiefs, towels, &c., used by the patient should be kept distinct from those used by others.

As regards *diphtheria*, many of the reports of the district M.O.H.'s refer to the difficulties met with in connexion with "carrier" and "return" cases of the disease, but the extended facilities afforded by the county bacteriological laboratory enable these cases to be controlled with a large measure of success. In Dr. Greenwood's view, no diphtheria patient should be considered free from infection until at least three consecutive negative swabs have been obtained. Dr. D. Macdougall, M.O.H., Ashford urban district, thinks that this district has more than its share of diphtheria, and suggests that the incidence of the disease might be reduced by improving the insanitary conditions which prevail and abating the nuisances caused by the large number of hand-flushed water-closets which are found in the area. Dr. J. Mathewson, M.O.H., Bromley, expresses the view that many cases of diphtheria are now diagnosed that would have been overlooked a few years ago at a time when no facilities existed for bacteriological investigation. On the other hand, most medical men have had experience of cases in which the result of examination of the swab has been contrary to their expectations. In Dr. Mathewson's view a more extended use of swabs in cases of sore-throat, in which there is doubt concerning the diagnosis, would be helpful; and in this connexion it is to be remembered that it not infrequently happens that the diphtheria bacillus is present in the nose while absent in the throat.

Dr. E. C. Warren (Gillingham) states that mild cases of diphtheria were observed with only small follicles on the throat, which were found positive on bacteriological investigation. Such cases are often neglected, and it is only when another member of the family develops a really bad throat that a doctor is called in. This emphasises the importance of medical advice in connexion with a sore-throat in any form.

Dr. R. McCombe (Margate) calls attention to unpaved yards as a predisposing cause of diphtheria. Children playing in these muddy places suffer from wet, cold feet, which often causes sore-throat and a consequent lowered state of vitality and resisting power. Much is being done, with the assistance of the property owners, to remedy these defects, but it is hoped that everyone will assist in this matter, which is one of common interest for the welfare of the town and its inhabitants.

Dr. G. M. Tuke (M.O.H., Hollingbourn rural district) reports an instance in which six cases of diphtheria occurred in one cottage. The source of infection was a child, who had had a sore-throat five weeks previously, and was most probably a "carrier." These "carrier" cases often retain the specific bacillus in their throats for long periods. Two such cases recently came under observation, which remained infectious for nearly 12 months, notwithstanding all the doctor's efforts.

URBAN VITAL STATISTICS.

(Week ended Feb. 26th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had increased from 12·3 to 15·4 in the four preceding weeks, further rose to 15·5 per 1000. In London, with a population of 4½ million persons, the death-rate was 15·1, or 0·9 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 8·8 in Swindon, 8·9 in Acton, and 9·0 in Northampton and in Preston, to 23·6 in Southport, 25·2 in Barnsley, and 27·8 in Hastings. The principal epidemic diseases caused 254 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 80 from infantile diarrhœa, 71 from diphtheria, 62 from whooping-cough, 29 from measles, 10 from scarlet fever, and 2 from enteric fever. Whooping-cough caused a death-rate of 1·6 in Walsall and 3·3 in Warrington. The deaths from influenza, which had been 61, 93, and 103 in the three preceding weeks, rose to 138, and included 30 in London, 15 in Portsmouth, and 8 in Sheffield. There were 3845 cases of scarlet fever and 2800 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3919 and 2808 respectively at the end of the previous week. During the week ended Feb. 19th 9 cases of encephalitis lethargica were notified in the County of London, and comprised 2 each in Islington and Bethnal Green, and 1 each in Paddington, Stoke Newington, Stepney, Wandsworth, and Camberwell. The causes of 43 of the 5516 deaths in the 96 towns were uncertified, of which 6 were registered in Birmingham, 4 each in Southport and Manchester, and 3 each in London and Stoke-on-Trent.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had increased from 14·9 to 18·2 in the three preceding weeks, further rose to 19·4 per 1000. The 443 deaths in Glasgow corresponded to an annual rate of 21·0 per 1000, and included 34 from whooping-cough, 19 from influenza, 4 from infantile diarrhœa, 2 from diphtheria, and 1 from scarlet fever. The 172 deaths in Edinburgh were equal to a rate of 20·1 per 1000, and included 5 each from diphtheria and influenza, 4 from measles, 2 from whooping-cough, and 1 each from scarlet fever and infantile diarrhœa.

Irish Towns.—The 147 deaths in Dublin corresponded to an annual rate of 18·1, against 18·2 per 1000 in the previous week, and included 3 from infantile diarrhœa and 1 each from enteric fever, whooping-cough, and diphtheria. The 154 deaths in Belfast were equal to a rate of 19·1 per 1000, and included 19 from whooping-cough, 2 from diphtheria, and 1 each from enteric fever, measles, and infantile diarrhœa.

Obituary.

E. C. LOMAS, C.B., D.S.O., M.B. VICT., F.R.C.S. EDIN.,

SURGEON-CAPTAIN, R.N.

THE death of Surgeon-Captain E. C. Lomas, though not unexpected by those who know the nature of his distressing illness, recalls the loss to the Naval Medical Service thus prematurely caused by his retirement in 1919. Born in December, 1864, and educated at Owens College, Manchester, he entered the Naval Medical Service in 1891, was awarded the D.S.O. for his work on the Ladysmith Relief Column, and was promoted to the rank of Staff-Surgeon, R.N. He had a unique experience in hospital ships. Before the war he was the senior medical officer of the *Maine*, the only hospital ship in commission, which was wrecked, in his absence on urgent family affairs, in the first half of 1914; he was also senior medical officer of H.M.H.S. *Rohilla*, totally wrecked late in 1914, and then subjected himself to much exposure; he was next in medical charge of H.M.H.S. *Garth Castle*, and in 1916 was made C.B. (Military) in recognition of his war services. In October, 1916, he organised and opened the Royal Naval Hospital at Granton, near Edinburgh. Here he did remarkably good work, his organising ability, his devotion to laborious detail, and his kindly tact being responsible for the efficiency, success, and happy spirit characteristic of the hospital. It is sad that a career of such successful achievement has been terminated before its full course has run.

PHINEAS SIMON ABRAHAM, M.D. T.C.D., F.R.C.S.I.,

CONSULTING DERMATOLOGIST TO THE WEST LONDON HOSPITAL AND MEDICAL COLLEGE.

Dr. Phineas Abraham, who died on Feb. 23rd at the age of 74, was a dermatologist of note. He was born at Falmouth, Jamaica, was educated at University School and College, London, at Trinity College and the Royal College of Science, Dublin, at the École de Médecine, Paris, and at Clausthal. He was scholar and exhibitioner at St. Bartholomew's Hospital, and won many other distinctions in his undergraduate career. His early experience was varied. Working first as a mining and chemical engineer, he became assistant in the Natural History Department of the British Museum, and in 1879 was appointed curator of the Museum of the Royal College of Surgeons in Ireland, where, after taking the Fellowship, he was appointed a member of the Court of Examiners. On graduating in medicine in 1886 he obtained the lectureship in physiology and histology at the Westminster Hospital Medical School and decided to specialise in diseases of the skin. First clinical assistant, then surgeon to the Hospital for Diseases of the Skin, Blackfriars, subsequently he was selected as medical secretary to the National Leprosy Fund and later became dermatologist to the West London Hospital. In 1910 he presided over the Dermatological Section of the B.M.A. annual meeting in London and he occupied for some years the chair of the West London Medico-Chirurgical Society and of the New London Dermatological Society. Dr. Abraham's knowledge of leprosy was nearly unique; he edited the Journal of the Leprosy Investigation Committee, and contributed articles thereon to Hillis's "Leprosy in British Guiana," to Allbutt's "System of Medicine," and to "A System of Syphilis." His dermatological writings are confined to the proceedings of several societies, but his translations of Unna have enjoyed wide circulation.

A friend of 30 years' standing writes of him: "A sound and successful clinician, Abraham *cured* his patients, and was not afraid to use the word, sometimes, I fear, to the annoyance of brother specialists. He was a tremendous worker, and spared no pains either in his laboratory or with his patients. Once during the war he spent nearly nine hours (with a short interval for lunch) over a bad case of diffused persistent acne, dealing with some hundreds of 'abscesses' individually with the happiest result to his patient, a young officer who had been sent home as incurable. He was one of the oldest and most loyal members of the Savage Club, many of whom have cause to be grateful to him for kindness both personal and professional, for he would accept no fee from a 'Savage.' An ardent Mason also and a Bohemian of the best type, his closest friends were to be found among artists of all kinds—actors, painters, sculptors, musicians, and journalists. With all these interests he was a devoted husband, father, and brother, for he lived for his family, and sympathy will be specially felt for his sister Ella, who devoted the whole of her life to him."

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Cmdr. H. Clift is placed on Retired List at own request, with rank of Surgeon Captain.

Lieut. D. W. Granet is transferred to Emergency List.

Surg. Cmdr. F. E. Bolton and Surg. Lieut.-Cmdr. G. L. Ritchie to *Southampton*; Surg. Lieut. J. F. M. Campbell to *Victory*.

ROYAL ARMY MEDICAL CORPS.

Major P. J. Marett retires, receiving a gratuity, and is granted the rank of Lieutenant-Colonel.

To be temporary Captains: E. G. S. Hall (late Captain, Spec. Res.) and R. Stephens (late temporary Captain).

Lieut. J. F. P. Gallagher resigns his commission.

Officers relinquishing their commissions: Temp. Major G. W. Beresford (retains the rank of Major). Temp. Capt. (acting Major) J. B. Butler (granted the rank of Major). Temporary Captains retaining the rank of Captain: I. Bidge-Jones, Z. A. Green, E. G. M. Gilchrist, W. Kirk, and H. H. McClelland. Temp. Hon. Capt. M. Bronk (retains the honorary rank of Captain). Temp. Lieut. J. A. B. Sim.

TERRITORIAL FORCE.

Capt. W. D. Carruthers, from 1st London (City of London) Sanitary Company, to be Captain.

Capt. B. J. Alcock resigns his commission and is granted the rank of Major.

Capts. W. G. Cook and L. T. Whelan resign their commissions and retain the rank of Captain.

INDIA AND THE INDIAN MEDICAL SERVICE.

Col. J. B. Smith to be Major-General.

The King has approved the retirement of Lieut.-Cols. W. W. Clemesha and C. C. S. Barry.

DONATIONS AND BEQUESTS.—Mr. Robert Francis Samuels, of Shaw-street, Liverpool, who has left property of the value of £11,346 net, has bequeathed £1500 to the University of Liverpool for three scholarships in medicine, surgery, and obstetrics and gynæcology; £200 to the Liverpool Royal Infirmary; £100 to the Queen Victoria Nursing Association; £200 to the Hospital for Women, Liverpool; £200 to the David Lewis Northern Hospital; £200 to the Liverpool Southern Hospital; and £200 to the Stanley Hospital, Liverpool. The residue is left to the executors for such persons, objects, or institutions as they may select.—Mr. Arthur Massingham, of Hove, Brighton, has left £100 to the Brighton, Hove, and Preston Dispensary; and £100 to the East Dereham Nurses' Home.—Mr. Henry Rutson, of Northallerton, has bequeathed £1000 to the Rutson Hospital, Northallerton, and £1000 to the York County Hospital.

VITAMINES AND COMMON SENSE.

To the Editor of THE LANCET.

SIR,—I am not one likely to underestimate the importance of the discovery of vitamines or "accessory food substances." The subject is one of such vital interest to the community that its immediate application to the problem of food has been at once grasped not only by the medical profession but by the public at large. Even *Punch* has. published a pleasant skit upon the subject. This popularity is not without its dangers, especially among those whose physiological knowledge is so scanty that they are apt to run the idea to death. The introduction of a new and taking term and all that it connotes is frequently the cause of a great deal of loose talk and reasoning. This certainly followed when the word hormone was coined, and Professor Cathcart, in his recently published book on the "Physiology of Protein Metabolism," when speaking of the vitamines, says:

> "There is at present a tendency to draw conclusions in a haphazard way, and attempts are being made to convert a valuable and interesting field of research into a happy hunting ground for the charlatan and the manufacturer of proprietary remedies."

May I expand this theme a little? The now well-known analogy which Professor F. G. Hopkins was the first to use, between the building of a wooden hut and the building of our body, comes in very handy here. The hut is built of planks, but the planks alone without nails are useless. The body is built of food materials, but the presence of a small amount of the vitamines (the nails) is indispensable. But who would dream of building a wooden house with nails only? Yet this is just the way some people are at present speaking; so impressed are they with the indispensability of the vitamines that they seem to have forgotten that the essential food principles (proteins, fats, carbohydrates, salts, &c.) are necessary also. I have, for example, heard of teachers of household science who know that the antiscorbutic vitamine is the one to which heat is most detrimental, advising their pupils to eat raw cabbage in preference to boiled vegetables. They would no doubt get more vitamine, but what about the starch and other constituents of the plant material? A great desideratum in the further exploration of the vitamines is, as Miss Harriette Chick pointed out some time ago, the employment of trustworthy quantitative methods. So far as such methods at present go, they all show that very minute amounts of the various vitamines suffice. In Professor Hopkins's pioneer work he succeeded in converting a useless diet compounded of pure proteins, fats, &c., into a useful and efficient one by the simple addition of 2 or 3 c.cm. of milk per diem. Boiling a potato or a cabbage for many hours will, in time, succeed in destroying all its vitamine, but who is there who wastes coal or gas in this way? Before and since the discovery of vitamines people have thrived upon cooked food, and there is no evidence to show that they were any the worse or suffered from scurvy or other deficiency diseases. Some of the vitamine evidently has escaped the destructive action of the heat which has been applied at a reasonable temperature or for a reasonable time. That which remains is evidently sufficient in all ordinary conditions. Common sense must be blended with the acquirement of physiological wisdom.

It is, however, in relation to milk that the question appears to be most urgent. Colonel R. J. Blackham, in a recent article in THE LANCET,[1] draws attention to it, and shows that in addition to confusion between the three known vitamines there is, even in relation to the antiscorbutic vitamine, the one to which heat is most inimical, considerable difference of opinion as to how much of it is destroyed at high temperatures; the balance of evidence is in favour of the view that this vitamine does not entirely disappear when the milk is raised to the boiling temperature. Does not this also coincide with experience? The use of heated milk, of boiled milk puddings, and the like, is no new departure. Are we in consequence afflicted to any great extent with scurvy or even with infantile scurvy?

The whole subject of pure milk is one very near to my heart. The importance of milk straight from the mammary gland of the infant's mother is a truism, but so long as mothers cannot or will not suckle their children, one has to fall back on the best substitute, in this country the milk of the cow. Here again it should be absolutely fresh and pure (suitably diluted of course), and not sophisticated either by addition of preservatives or by subtraction of one or other of its ingredients. But in the present state of legislation this ideal condition is difficult to realise. Some measure of protection against disease germs carried in the milk must be adopted, and the simplest precaution of all is that known as pasteurisation. I am quite aware that the quantity of the antirachitic factor (vitamine C) in milk is not very great, and that its entire removal by the drastic agencies employed in the manufacture of some dried milks is followed by outbreaks of infantile scurvy. Although I am open to conviction that the repeated heating of milk is open to the same objection, I cannot see that the simple process of pasteurisation is the danger that some extremists allege it to be. Better to run the risk of some lessening of the vitamine, for probably enough will be left to make it still efficacious antiscorbutically, than to run the much more serious risk of conveying by the milk the germs of fatal disease. Again, it is necessary to blend common sense derived from experience with the application of new-found facts, however important they may be.—I am, Sir, yours faithfully,

W. D. HALLIBURTON.

King's College, London, Feb. 24th, 1921.

DUST IN EXPIRED AIR.

To the Editor of THE LANCET.

SIR,—The efficacy of the air passages as a trap for the removal of suspended matter in the air has been generally assumed to be very high. Tyndall is quoted as stating that expired air was optically pure, and, generally speaking, the assumption is made that air entering the lungs through the nose is purified from all suspended matter before it reaches the deeper parts of the lungs.

Having some doubts as to the truth of this assumption I made a few experiments to ascertain what the facts of the case were. Using the standard instrument described in the third report of the Advisory Committee on Atmospheric Pollution[1] I tested, on Nov. 17th last, a sample of air during a slight smoke haze in London. The air was found to contain approximately 1·92 mg. per cubic metre. I then filled a small rubber balloon with ordinary tidal expired air, taking care that the balloon was washed out by filling with expired air and emptying several times before testing. It was then blown up with air breathed in through the nose as in ordinary respiration, the balloon was fixed on the filter and a record obtained from the contained expired air. This was found to contain 1·28 mg. per cubic metre. Thus, in ordinary breathing the expired air contained about 70 per cent. of the suspended impurity which entered during inspiration. Doubtless, some of the suspended matter in the expired air was deposited on the walls of the balloon, but this would be a very small percentage of the total and would not invalidate the general results.

A similar experiment was then made, but in this case instead of "tidal" air, "reserve" air was used; the balloon was thoroughly washed out with "reserve" air and then filled after the end of a long inspiration, the air in each case being drawn in through the nose. The balloon was attached to the instrument and a record obtained which showed that the "reserve" air contained about 60 per cent. of the dust in the inspired air.

---

[1] Supplement to THE LANCET, March 23rd, 1918.

In order to check these observations I used an apparatus by means of which a very small jet of air could be blown upon a microscope slip; the jet was about 1/100 in. in diameter and impinged upon the slide at a distance of about 1/16 in. The result of causing such a jet of air to strike the slide is that a certain proportion of the suspended particles strike and adhere to the slide, so that a few cubic centimetres of ordinary London air directed against the slide are sufficient to produce a black spot, quite visible to the naked eye.

Using this instrument I repeated the observations, both with expired "tidal" air and with expired "reserve" air, taking all precautions to avoid fallacies in the experiment. In each case from the expired air I obtained a black deposit upon the slide. A sample of ordinary London air projected against the slide was examined microscopically and it was found that the particles were all black and varied in diameter between 1/100,000 and 1/20,000 of an inch. Slides obtained from expired air were also examined and the deposit was found to consist of similar black particles of similar dimensions.

It seems certain, therefore, that the suspended matter in the London air is not entirely removed by the action of the respiratory passages, but only about 30 per cent. is so removed. I am, Sir, yours faithfully,

Victoria-street, S.W., Feb. 22nd, 1921. J. S. OWENS.

PSEUDO-COXALGIA.

To the Editor of THE LANCET.

SIR,—I confess to having been rather puzzled about the treatment of pseudo-coxalgia, and I would like to make one or two remarks *à propos* of Mr. H. A. T. Fairbank's paper (THE LANCET, Jan. 1st), and Sir Henry Gauvain's letter (Feb. 19th).

One of my earliest cases of this condition was that of a boy who presented typical signs on both sides—the skiagrams showing characteristic changes in the head of each femur. By my direction he was kept recumbent for several months with weight extension on the legs, and, by way of exercise, he had massage and movements daily. Eventually he recovered with no deformity and perfect movements of the hips in all directions—the skiagrams now showing complete regeneration of the head of the femur on both sides. This is what I understand by "recovery" in pseudo-coxalgia. I have since been told by various kind friends and colleagues that my treatment was, to say the least of it, superfluous; that it is quite unnecessary to keep these cases off their feet, or, indeed, to treat them at all; because they all get well without treatment. Yet, on at least three occasions recently I have been shown skiagrams of "the late results of pseudo-coxalgia." These all showed a very ugly deformity of the hip. The head of the femur was mushroomed and grossly deformed, and there were shortening and limitation of movement at the hip-joint; in fact, obvious disability.

So when I read that "the progress of the case is always towards recovery"; that "most writers agree that treatment, or entire absence of treatment, has little, if any, effect on the ultimate result"; and that "finally there may be some mushrooming of the head of the femur"; I am tempted to ask what is meant by "recovery" in this condition. Sir Henry Gauvain points out that these cases do not die, "nor is permanent disability, other than slight shortening and limitation of abduction, to be anticipated." But neither do cases of scoliosis die, yet we should hardly be justified in saying that a case of scoliosis has recovered because it happens to be alive after a few years.

During a recent visit to this country Professor Calvé remarked that treatment (of pseudo-coxalgia) is unnecessary, as they all get well without it, and he added, "Of course, they limp"—as though it was the most natural thing in the world that a child should grow up with a short limb, a limp, and limited movement at the hip-joint. Most orthopædic surgeons have seen a good many cases of this condition by now, but few of us have the opportunity of seeing any number of them grow up from childhood to adult age. It is very desirable that the end-results of untreated cases should be recorded. It is said that after a time "the ossification of the epiphysis returns to the normal, until at last the hemispherical shape of the ossific centre is restored." This may be so in some cases, but is it the rule, can it be relied upon in untreated cases? If not, how should these cases be treated? I know that weight may be taken off the hip-joint by a skilfully and accurately fitted calliper splint or a Hessing's splint. But I know, too, that there is a good deal of make-believe and self-deception in the common use of these splints especially in growing children. I question whether the calliper splint, as ordinarily used, is really efficient in preventing deformity of the head of the femur, and one would like to see recorded the end-results of cases treated by this method. Meanwhile, it would not be a bad plan to consult the parents of some of these children (especially in private practice) as to whether a little limp, a little shortening, and some limitation of movement at the hip, are really nothing to them. I strongly suspect that if any orthopædic surgeon had to treat a child of his own for pseudo-coxalgia he would take very good care that no weight came upon that child's hip-joint, and he would be very chary of trusting to the ordinary calliper splint until the head of the femur was well on the way back to normal.

I had almost been persuaded that my treatment of these cases was wrong, in fact, superfluous, when I saw the skiagrams of late results already mentioned. But I now require a good deal more evidence that treatment is useless before I abandon it. I realise, of course, that in hospital cases we may be driven by lack of accommodation to methods which are perhaps only second best. But we ought to be clear about what is really the best and, therefore, the proper treatment.

I am, Sir, yours faithfully,
A. S. BLUNDELL BANKART.

Harley-street, W., Feb. 23rd, 1921.

THE BRITISH PHARMACEUTICAL INDUSTRY: AN APPEAL TO MEDICAL MEN.

To the Editor of THE LANCET.

SIR,—We, the undersigned old-established British houses, earnestly appeal to medical men of the British Empire to support British industry to the utmost of their power. This appeal has no political foundation. We wish simply to place before your readers a few facts for their most careful consideration:—

(1) In all fairness it should be realised that international trading is not on a reciprocal basis, that is to say, foreign chemicals and pharmaceutical preparations are admitted into this country, practically speaking, duty free, whilst goods exported from this country to countries abroad are subject to an exceedingly high ad valorem duty. One vast country we have in mind directly prohibits the import of pharmaceutical preparations of other countries, while other immense States do so indirectly by means of the high duty already referred to.

(2) It should be remembered that, although much has been done during the war and since in the direction of promulgating British chemical industry, a great amount of work has yet to be done to consolidate the fine chemical and allied industries at home, and an obvious point is that the factories in Germany are for the most part absolutely intact and she retains secrets which are the outcome of laborious, painstaking investigation.

(3) We desire to respectfully impress on your readers that we do not advertise to the public, nor "prescribe," nor in any way trespass on the rightful province of the medical practitioner; on the contrary, we rely on the position that the chemist, so far as the medical use of chemicals is concerned, is the handmaid of the medical man, and we might add, rather bluntly, we do not recommend foreign medical men and health resorts; why should the medical man recommend foreign pharmaceutical preparations?

(4) The scientific staffs in our laboratories welcome suggestions from medical men, and will carry out investigations to elucidate problems connected with chemistry, materia medica, and the like which may prove of assistance in the art of healing.

(5) We have in our employment men who have been through the hell of the recent war. We have also with us young pupils and apprentices who had never even heard the name of Lister and who knew nothing of his teaching until we taught them what he did for suffering humanity. These two types of men, in our opinion, need every support, encouragement, and protection which the medical man can give.

We ask the doctor to demand British produce and, furthermore, convince himself that what is stated to be British *is* British, and by so doing enable us to give employment to more and yet more British workmen and to compete with foreign enterprise on the unequal footing above mentioned.

We are, Sir, yours faithfully,

THE SEPARATION OF PRESCRIBING AND DISPENSING.

To the Editor of THE LANCET.

SIR,—In reply to the letter of Mr. J. O. Braithwaite in your issue of Feb. 26th, the Ministry of Health Committee of the Pharmaceutical Society admits, in its report which appeared in the *Pharmaceutical Journal* of May 15th, 1920, that the only statutory qualification in the dispensing of medicines is that held by the apothecary's assistant, also that the statutory qualification of the pharmacist for the dispensing of poisons applies only to open shops, and only to scheduled poisons. A hospital or institution cannot be held to be an open shop. If there is to be any separation of prescribing and dispensing the apothecary's assistant can justly claim priority to dispensing in any places other than open shops.

I should like to point out that in the orders governing the appointment of dispensers to many public hospitals, institutions, &c., the apothecary's assistant is equally eligible with the pharmacist, and in order of precedence appears before the pharmacist, and further, as a matter of fact he discharges his duties in these places to the entire satisfaction of those concerned. Mr. Braithwaite seems to have overlooked the fact that the business of a chemist and druggist has many things in common with the herbalist and grocer, and if such classification is necessary the pharmacist certainly has the prior claim.—I am, Sir, yours faithfully,

H. C. RICHARDS,
Hon. Secretary, Association of Certificated Dispensers.
Hathaway-road, Croydon, Feb. 27th, 1921.

RACIAL TUBERCULOSIS SUSCEPTIBILITY.

To the Editor of THE LANCET.

SIR,—In an annotation in THE LANCET of Nov. 30th, 1920, figures are quoted from a paper by Professor S. le Cummins, contrasting the rates for tuberculosis [illegible] British Army with the much higher rate which [illegible]iled amongst the men of the South African Labour [illegible], and using these as an illustration of the susceptibility of primitive races to a new disease and their inability to withstand its attack. This use of the figures is not justifiable in regard to South African natives at all events. In a paper written in 1911, a précis of which appeared in THE LANCET of May 11th, 1912, I gave evidence to show that the great susceptibility of South African natives to pneumonia and tuberculosis was due to the great prevalence of a syphilitic taint in all native tribes in South Africa, and that they took these diseases in a virulent form. In a subsequent paper (THE LANCET, April 11th, 1914) it was shown that a similar susceptibility, in a somewhat less degree, applied to the white population also. The ancient and often-quoted example of the heavy mortality resulting in a "virgin soil" from such a disease as measles is easily understood by anyone who knows the habits of natives when suffering from any febrile disease without putting the onus therefor on the "virgin soil," as Professor Cummins seems to do.

I am, Sir, yours faithfully,

Clocolan, O.F.S., South Africa, Jan. 6th. B. G. BROOK.

AS OTHERS SEE US.

To the Editor of THE LANCET.

SIR,—The letter with this title by Dr. Harry Roberts in THE LANCET of Feb. 26th has touched me in a marked degree. The author of "Chronicle of a Cornish Garden," a fellow-student of mine some 30 years ago, concentrated his early energies in the congenial air of a wide and wild part of England, only to remove later to the drab and depressing atmosphere of an East-end district. No wonder he unconsciously contrasts, in his mind, the almost undisguised worship of a simple and kindly country-folk with the more shrewd and critical audience of the town wage-earner. Perchance if he had practised first in the sordid surroundings of some vast city and then transferred his sphere of action to the free and open country his opinions might have been reversed, and he might even have thought the status of the general practitioner had risen rather than descended.

But there is great truth in his letter. The political reformer who dreams wonderful visions of an ideal organisation for both the public and the practitioner is usually just the man who has never had any personal experience of private practice. How many general practitioners, I would ask, represent our profession in Parliament? As is usual among this type of man, in his overflowing enthusiasm and concentration he does everything of which he can possibly think but "the one thing needful." The machinery is all most perfectly made, of the finest metal, intricate, beautiful and wonderful, but, alas, those little drops of oil, that are so essential for it to run smoothly and wisely, have been forgotten, and sooner or later it is doomed to be placed on the scrap-iron heap. The vital factor in the life of medical practice is the relationship between the doctor and his patient. You may organise veterinary surveillance for a flock of sheep or goats and they cannot demur. Human beings are different. They can and will demur. The panel kills or stifles that fine professional relationship which every self-respecting medical practitioner unconsciously seeks. The patient, instead of being an individual, becomes merely an integer. The democratic Briton, whoever he may be, will not tolerate this. He has to put up with it for a time, as there is nothing else to fall back upon, but eventually, I feel convinced, he will resist it to the uttermost.

I agree with Dr. Roberts that by far the vast number of practitioners are keenly alive to the Hippocratic oath, and by far the majority, under particularly adverse circumstances and often against tremendous odds, will maintain and dominate an almost intolerable position, rather than sink to the level of the mean and, may be, squalid surroundings in which they may be placed. Although not on the panel, 20 years ago I tasted the difficulties and position of a country "club-doctor." A certain number of club members take up an attitude that because you are a club-doctor you are unable or unwilling to do justice to them on account of the small fees paid. Their prejudice leads them to think they are not receiving the best attention and, in the case of a protracted illness they will sometimes call in another doctor who they imagine may render them greater assistance, as they will be paid for their services by "piece-work." This, in many cases, is most disheartening for the club-doctor who is giving his best attention under, perhaps, difficult and adverse circumstances. What is he to do? He is in the grip of a relentless system over which he has no power to cope. And yet there are others. One, in particular, I remember, who after a long illness, from which he slowly recovered, told me: "I shall always respect you, Sir, for what you have done." This, from Dr. Roberts's view-point, was a success, though from a materialistic standpoint, no doubt, was a failure.

In practices such as Dr. Roberts appears to have it is a constant and continuous "casting of one's bread upon the waters," but I do believe if we are faithful to the highest ideals of our profession, we see it back again, even though it may be "after many days." One can only have unceasing admiration for those of our profession who are fighting to keep alive their spirit-instincts among an uncongenital society and in impossible surroundings. Are they not the very salt of our profession and are not these the men that have given to our profession in the past the splendid name it has won and will, we believe, carry it on unblemished to the end of all time?—I am, Sir, yours faithfully,

Crouch End-hill, N., Feb. 26th, 1921. T. WILSON PARRY.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—The time was ripe for the leading article on referred pain which appeared in your issue of Jan. 22nd, as is shown by the interest it has evoked. The rôle of a nerveless automatism in visceral action had been played out, and if a few actors still reluctantly withdraw from that deserted stage and with a silence with which positions once held are abandoned, the curtain is descending and the footlights on that play are growing dim. But all the bustle of an entertaining piece still animates the discussion of the parietal expression of visceral pain. The interest, moreover, in this matter is not only professional, for a long-suffering public, rendered valetudinarian, is regaled with this mystery even by the lay press, the *Times* being most obtrusive in its adulatory appreciation of the parietal interpretation of visceral pain. In due course, however, and with a like conclusion, the curtain will descend on this piece also, for the anatomical fates have decreed it, and they are, on the whole, more reliable prophets than either physiological or clinical vaticinators, although of the latter the clinical may, perhaps, be regarded as the more trustworthy.

The conclusion reached in your article is that viscera are capable of being the site to which pain is referred under certain circumstances, notwithstanding the well-known peculiarities of their sensibility. You, therefore, subscribe in this matter, and I think with more justice than is often the case, to the truth of the saying, *Securus judicat orbis terrarum*. That is, that the "man in the street" with nephritic colic or angina pectoris is aware that he is not suffering from a dermic or hypodermic neurosis, but from a deeper visceral pain. As you remarked in an editorial note on the letter of one of your correspondents (Feb. 6th), this chief point has been ignored by most of your correspondents, who appear to be more occupied with the existence and diagnostic value of the parietal and segmental tenderness which is, at times, the aftermath of an orginally deeper suffering.

The exception to these is your last correspondent, Sir Clifford Allbutt (Feb. 26th), who bases his views on the embryology and innervation of the serous surfaces or "inpacked" "skin" which forms the capsule of the viscera; hence, he demurs to Dr. A. F. Hurst's conclusion, that the viscera are themselves sensitive, given an "adequate stimulus." *To accept Sir Clifford Allbutt's* view would be to agree that, unless the investment of viscera be affected, there can be no visceral pain and that all intrascapular visceral innervation is motor in character or function. Even the acutely painful thrombus in a coronary artery hurts, according to him, because of a stretching of the pericardium, which he regards as ensuant. How does this conclusion agree with Cannon and Washburn's demonstration of the association of hunger-pains with gastric contraction? In this case the capsule is relieved of tension during the pain not stretched. The tension here is in the contracting muscle.[1] From clinical evidence it may be asserted with confidence that pain *during an attack*, whether of angina pectoris, acute appendicitis, nephritic or biliary colic, or any other visceral agony is *deep* and referred by the patient, as well as determinable by the physician, to be subparietal. The surface aftermath but proves that the circumstances which induce visceral pain reveal the existence of paths in the autonomic nervous system afferent to centres, spinal and cerebral, which are usually denied to exist except in very limited numbers. That the visceral nerves are mixed nerves may, however, be shown anatomically.

More than 20 years ago, when delivering the Morison lectures in Edinburgh, I showed that "the nerves which innervate the pia mater are anatomically similar to those which follow, twist round and end on vessels, and may occasionally be actually seen to take their departure from the nerve on the vessel." It will be *admitted that if the vessel be a motor organ the* pia mater certainly is not, and that its innervation therefore belongs *to the sensory group, however* modified from the somatic type of the same series. I may remark, in parenthesis, that the intracranial vessels were at that time regarded by physiologists as nerveless and muscular automata. They played, indeed, a leading part in the drama now withdrawn, to which I have already referred. I have also shown that the innervation of the coronary artery is submuscular as well as perimuscular—intravascular as well as extravascular—and *that the mode of termination of visceral* nerves, whether capsular or intracapsular, is the same.[2]

My anatomical and clinical experience, therefore, has strengthened me in the position I have long maintained and published, on what have appeared to me to be sufficient grounds—namely, that the site of visceral pain may be not only capsular or peri-organic but also intracapsular and organic. With this view the leading article already referred to seems to be in agreement, although it does not appear to show acquaintance with my work.—I am, Sir, yours faithfully,

ALEXANDER BLACKHALL-MORISON.

London, Feb. 27th, 1921.

JOHN HOWARD McFADDEN.

To the Editor of THE LANCET.

SIR,—A tribute is due to the memory of John Howard McFadden, who died at Philadelphia on Feb. 16th, aged 70. He was an unostentatious philanthropist who helped to make progress. Although he was attacking a problem which he could scarcely hope to solve, he cheerfully started and entirely supported for six years a cancer research *organisation* at the Lister Institute of Preventive Medicine in London. He gave carte blanche, and later on extended the investigations to other branches of medical research—for example, sending expeditions to investigate pellagra in the United States. The researches made in association with the Home Office into the cause of industrial cancer at briquette works are to the credit of Mr. McFadden, who received the thanks of the Secretary of State for what he called his "spade-work," but he never courted publicity. He was a remarkable *personality*. Equally known in the great cities of Europe and America, he was a sort of "Mr. Potter of Texas," with the sombrero replaced by a silk hat and the revolver by kindness. A cotton magnate, he enjoyed to act the part of an American millionaire. He was a daring speculator, being usually *"bullish"* when others were "bears," and on one occasion at least he averted a panic in the Cotton Exchange in New York by his sheer force of personality. He was a judge of pictures, and collected a fine gallery of eighteenth-century English art. By medical men he will be remembered for, among his many activities, his practical interest in medical research.

I am, Sir, yours faithfully,

Curzon-street, W., Feb. 26th, 1921. H. C. ROSS.

Wednesday, Feb. 23rd.

Indian Medical Service and Cadre Acceleration.

Mr. Rupert Gwynne asked the Secretary for India whether he was aware that the Indian Medical Service had received neither the benefits of the accelerated cadre promotion granted in the British Army and the Royal Army Medical Corps or the accelerated time promotion granted in the Indian Army; whether the reason given for the exclusion of the Indian Medical Service from the British Army and Royal Army Medical Corps cadre acceleration to lieutenant-colonelcy was because the Indian Army did not have it, and from the Indian Army time scale acceleration to field rank because the Royal Army Medical Corps did not have it; and what was the object of placing officers of the Indian Medical Service in this disadvantageous position.—Mr. Montagu replied: I find some difficulty in understanding the honourable Member's question. Perhaps he could furnish me with particulars of any specific case on which it is based. Meanwhile I can assure him that there has been no discrimination against the Indian Medical Service.

Ministry of Health Bill.

Mr. Ormsby-Gore asked the Minister of Health whether he proposed to reintroduce the Ministry of Health (Miscellaneous Provisions) Bill in the form in which it was rejected by the House of Lords last session; and, if so, when.—Dr. Addison replied: I propose to introduce as a separate Bill the housing portion of the Bill of last session. I am not at present in a position to state the course that will be taken with regard to the other portions of the Bill.

Local Medical Officers' Salaries.

Mr. Mosley asked the Minister of Health whether it was the practice of the Ministry of Health to abrogate agreements regarding salary arrived at between local councils and their medical advisers and to raise these salaries, without consulting in any way the ratepayers of the district. -Dr. Addison replied: The answer is in the negative.

Dr. M'Donald asked the Minister of Health if, in order to obtain true health statistics of the nation, he purposed ultimately issuing record cards to the whole population and not, as at present foreshadowed, limiting the issue to insured persons.—Dr. Addison replied: I do not think that it is practicable to give effect to the honourable Member's suggestion.

Spahlinger Cure for Consumption.

Mr. Lynn asked the Minister of Health whether he was in a position to give any information regarding the Spahlinger cure for consumption.—Dr. Addison replied: I have made full inquiries regarding this supposed remedy for tuberculosis, but it is clear that much further investigation and experience will be necessary before accepting the claims made for it. It appears that as long ago as 1913-14 the serum in question was prepared. It was tried by several hospital physicians, but there is not yet sufficient evidence of its therapeutic value, nor have the trials of it been sufficiently extensive to justify any definite and reliable conclusions. I understand that a report on the method of treatment has been presented to the French Academy of Science, and if and when supplies of the serum become available for investigation in this country I shall be prepared at once to facilitate and coöperate in an exhaustive examination of its efficacy both from laboratory and clinical points of view. I understand that a supply of the serum is not likely to be available for this purpose for some months, and that on account of the secrecy maintained as to its constitution and method of preparation it has hitherto been found impracticable for the recognised research laboratories in this country to investigate its properties and effects.

Infectious Cases in Bedwellty Area.

Mr. Charles Edwards asked the Minister of Health whether the medical officer of health for the Bedwellty area reported nine cases of scarlet fever and one case of diphtheria for the week ending Jan. 22nd, 1921; if so, why were these cases not reported in the weekly summary of returns of certain specified infectious diseases; whether he was aware that for two months Bedwellty had been marked "Nil" in the Report, which was not in agreement with the returns sent in by the medical officer.—Dr. Addison replied: The honourable Member is under a misapprehension. The cases in question were not included in the weekly summary because the returns of these cases were not received from the medical officer of health in time for their inclusion. The district in question was not, however, marked "Nil" in the summaries, but as "Returns not received." The figures thus omitted from the weekly summaries were, according to practice, included in the monthly supplementary statements for the periods concerned.

Charges to Panel Patients.

Mr. Robert Young asked the Minister of Health whether his attention had been drawn to the case at Old-street police-court where it was elicited that a panel patient had to pay 2s. 6d. for each visit she made to the doctor because she could not afford to leave her work to attend at the surgery during the hours fixed for panel patients, and what steps he proposed to take in this and similar cases.—Dr. Addison replied: My attention has been called to this case which I learn is under investigation by the London Insurance Committee. In all cases where complaint is made that a doctor has improperly charged a fee to an insured person the matter is referred for investigation by the Insurance Committee to the appropriate tribunal set up under the Regulations for dealing with complaints with a view to the necessary disciplinary action if the complaint is established.

Ministry of Health Secretary's Salary.

Sir Thomas Polson asked the Chancellor of the Exchequer whether the salary of the first secretary of the Ministry of Health had recently been increased from £2000 to £3000 per annum, and that of the second secretary from £1700 to £2200; and if he would state on what grounds these increases had been made.—Mr. Chamberlain replied: The salary of the first secretary to the Ministry of Health has been increased from £2000 plus £750 bonus to £3000 plus £500 bonus, and that of the second secretary from £1700 plus £750 bonus to £2200 plus £500 bonus in pursuance of the recommendations of a Committee appointed by the Government to advise them as to the emoluments which should attach to the principal permanent posts in the Civil Service. My right honourable friend the Member for Paisley (Mr. Asquith) was good enough to act as chairman of the Committee.

Military Service and Attributability.

Mr. T. A. Lewis asked the Minister of Pensions whether the Ministry could see its way to lay down the principle that any man who, entering the army in sound health, was discharged in impaired health should have his invalidity automatically attributed to military service.—Mr. Ian Macpherson replied: I am not prepared to accept this suggestion. Each case is considered on its merits in the light of all available evidence, and if a claim to pension is rejected by my department on the ground that the disability is not due to service, the man has a right of appeal to an independent tribunal.

Coroners (Remuneration) Bill.

Sir T. Bramsdon introduced a Bill to amend the law relating to the remuneration of coroners. The Bill was read a first time.

Thursday, Feb. 24th.

Pension Appeals to House of Lords Tribunal.

Mr. John Guest asked the Minister of Pensions if he would state how many cases of appeal against pension decisions by discharged Service men were dealt with by the House of Lords Appeal Tribunal during the year ending Dec. 31st, 1920; if it was the practice when such appeals were heard for a discharged man to sit on the tribunal; if it was not the practice, how many cases were dealt with during the above period without an ex-Service man on the tribunal; if he would state how many cases of appeal by ex-officers against pensions decisions were dealt with by the House of Lords Appeal Tribunal during the same period; if it was the practice for an officer to sit on the tribunal; and, if it was not, how many cases were heard during the above period without an officer on the tribunal.—Major Tryon (Parliamentary Secretary to the Ministry of Pensions) replied: I am informed that during the year 1920 the Pensions Appeal Tribunals heard and disposed of 344 appeals from officers and 13,557 from men. The answer to the second part of both these questions is in the affirmative. It is, in fact, not merely the practice, but a statutory requirement.

Ministry of Pensions and Tuberculous Ex-Service Men.

Dr. M'Donald asked the Minister of Pensions if he would reconsider his attitude towards ex-Service men who had been certified as suffering from tuberculosis shortly after their discharge from the army on account of being unfit for further military service and now considered ineligible for pension; whether he was aware that, while the health of some men was improved by service, the health of others was deteriorated, thus paving the way to tuberculosis; and whether cases of this character would be dealt with more sympathetically, notwithstanding the decision of any medical board examining these men months after their discharge.—Major Tryon replied: My right honourable friend is not aware that claims to pension on the ground of tuberculosis are unsympathetically considered. If the tuberculosis develops within a short period of discharge the disablement is generally admitted to be either attributable to or aggravated by service, and even where the disease does not develop until after a considerable period the circumstances of the man's military service and of its effect on his health are carefully examined. If the Ministry are unable to accept his claim the man is advised of his right of appeal to an independent tribunal.

Disabled Men and Form M.P.M.D.S. 29.

Lieutenant-Colonel WALTER GUINNESS asked the Minister of Pensions whether he was aware that great difficulty was caused to men drawing allowances when under treatment at home but unable to work in finding persons in responsible positions to witness the form M.P.M.D.S. 29, as the witnesses almost invariably understood that in signing the document they were vouching for the accuracy of the man's statement; and whether, in view of the undertaking on the form that the pensioner will at once notify the local committee if he undertook paid work, the Ministry of Pensions would limit the obligation to complete the form every week to those men who were able to work, but who were required on medical grounds to abstain from using their earning capacity, and that in the case of those where the medical certificate showed total incapacity for work the form should only be completed each time the man came up for review by the medical referee.—Major TRYON replied: The form M.P.M.D.S. 29, to which my honourable and gallant friend refers, is now under revision, and consideration is being given to the difficulty stated in this question.

Pensions Appeal Delays in London Region.

Lieutenant-Colonel Sir FREDERICK HALL asked the Minister of Pensions if he was aware that there was delay in appellants having their cases heard before an appeal tribunal, particularly in the London region; whether recommendations had been made for considerable increase in the number of these courts; if he could give any reason why there had been such delay in recommendations being carried out; and what steps it was intended to take to remedy this unsatisfactory state of affairs.—Major TRYON replied: I am informed that two extra courts are now sitting and that two more will begin sitting next Monday. The question of still further increasing the number of courts is now under the consideration of the Lord Chancellor.

Captain Sir DOUGLAS HALL asked the Minister of Health if, as the result of an earlier system of record cards of insured patients, the cards proved to be useless and were practically unexamined, large quantities of cards being sold as waste paper; and did he anticipate a better fate for the new cards.—Dr. ADDISON replied: Under the earlier system of record the cards were by no means useless and were destroyed only after having served their purpose, but their value for clinical purposes was greatly impaired because at the end of every year they were surrendered and the particulars as to the names of patients and their illnesses separated. It was because of this inherent defect in the old cards that the new records have been designed by a committee mainly composed of members of the medical profession who gave fuller place (and in my view rightly so) to the clinical objects of the record, and so designed a form which might serve as a continuous record of insured persons' illnesses. These records will undoubtedly be of great value, and I may add that the keeping of them gives insurance practitioners less work than the old records.

Dangerous Drugs Act Regulations.

Mr. HANNA asked the Minister of Health whether he had received numerous resolutions and letters of protest from associations of and individual chemists in the north of Ireland against certain parts of the regulations under the Dangerous Drugs Act; and, if so, would he say what action he proposed to take in the matter.—Mr. SHORTT (Home Secretary) replied: A number of representations have been received from chemists and associations in the north of Ireland. As regards the action which is being taken in the matter I would refer the honourable Member to previous replies on the subject.

Mr. CLOUGH asked the Secretary for the Home Department if he would state what was the result of the submission of the preliminary draft of the regulations under the Dangerous Drugs Act by the Home Office, as stated by the Under Secretary of State in the press on Feb. 9th, to the Pharmaceutical Society of Great Britain, the Pharmaceutical Society of Ireland, the General Medical Council, the Royal College of Physicians, and the Royal College of Surgeons; whether, prior to the publication of the draft regulations by the Home Office, any and, if so, which of those bodies had indicated their approval of the draft; and whether any and, if so, which had submitted objections.—Mr. SHORTT replied: The result of the communication of the preliminary draft in November last to the bodies mentioned for their observations was as follows. The Royal College of Physicians and Royal College of Surgeons considered the draft satisfactory and offered no observations, except that the Royal College of Physicians thought the minimum limit in the case of cocaine (which is fixed by the Act and cannot be altered by regulation) too high. The General Medical Council also approved the regulations, but asked that the directors of research laboratories might be included among the classes of persons who are authorised by the regulations themselves to be in possession of the drugs. The Pharmaceutical Society of Great Britain replied by a letter maintaining that the proposal in the regulations to prohibit the sale of the drugs to the public except on a medical prescription was ultra vires of the Act, and proposing that before going on with the regulations the Government should appoint a committee to consider the desirability of separating the functions of prescribing and dispensing. The reply of the Pharmaceutical Society for Ireland, which was not received till after the draft had been published, submitted objections on various points.

Admiralty Surgeons' Fees.

Captain ELLIOT asked the First Lord of the Admiralty if he would state when it was intended to revise the scale of fees paid by the Admiralty to surgeons and agents (Article 21, Clause 3), seeing that these fees were below those paid by other departments and had not been revised for 35 years, notwithstanding the enormous increase in the cost of living. —Sir JAMES CRAIG (Parliamentary Secretary to the Admiralty) replied: A revised scale of fees is now under consideration, and it is hoped that a decision may be reached and promulgated very shortly.

Industrial Fatigue Research Board.

Captain ELLIOT asked the Lord President of the Council whether the Treasury had ordered the Industrial Fatigue Research Board to be wound up by March; whether this body had recently issued a most valuable report on conditions in the steel-making industry, indicating methods for securing greater efficiency in production; whether it was the case that the dissolution of this body now would mean the loss of all the work and money spent in getting it to the present point when it was beginning to show a return; and whether, in view of these facts, he would take steps to prevent the total destruction of this Board.—Dr. ADDISON replied: The matter referred to is now under consideration, and if my honourable friend will repeat his question next week I hope to be able to give him a definite reply. The Government entirely shares his view as to the report in question.

FRIDAY, FEB. 25TH.

Food Values.

Captain ELLIOT asked the Minister of Health whether he would consider whether information regarding nutritious and economical foods could be circulated to local authorities, educational authorities, and the press, in view of the present distress and the great amount of manufactured and semi-manufactured foods consumed by the people of this country. —Dr. ADDISON replied: I am considering whether it would be practicable to issue a pamphlet containing information on the lines suggested by the honourable Member. As he is aware, it is difficult to make any general statements with regard to the values of food which are not liable to be misconstrued. I am having certain researches conducted on the subject in collaboration with the Medical Research Council.

Dangerous Drugs Act Regulations.

Lieutenant-Colonel WALTER GUINNESS asked the Secretary for the Home Department whether the draft regulations under the Dangerous Drugs Act provided that no prescription given by a veterinary surgeon could be dispensed; and what provisions were made in the regulations enabling farmers and stock breeders to be in possession of the drugs for the purposes of administering them to their stock.—Mr. SHORTT replied: The draft regulations provide generally for the issue of licences or authorisations in proper cases and I propose to insert words in the regulations expressly authorising the supply of the drugs for the purposes of the treatment of animals on the prescription of a veterinary surgeon. Further details as to the application of the regulations to agriculture are under consideration in consultation with the representatives of the agricultural interests.

COLSTON UNIVERSITY RESEARCH SOCIETY.—At a recent meeting of the University Colston Society Committee it was decided to alter the title of the society to Colston University Research Society. The society was founded in 1899, and on the establishment of the University of Bristol the decision was made to apply the funds of the society to the support of research work within the University. The new title has been adopted in order to make it clear that the society exists to support research work within the University and that the funds are devoted entirely to facilitate and extend this work. The annual dinner of the society is fixed for May 23rd. The president this year is Alderman Frank Sheppard, and Sir William Bragg, F.R.S., Quain professor of physics of the University of London, will be the guest of the society.

Medical News.

ROYAL INSTITUTION OF GREAT BRITAIN.—The Friday evening discourse on March 11th will be delivered at 9 o'clock by Dr. John Freeman, on Medical Idiosyncrasies. A general meeting will be held at 5 P.M. on Monday, March 7th.

ROYAL SOCIETY OF ARTS.—Three Cantor lectures will be delivered on March 7th, 14th, and 21st, at 8 P.M., at the house of the society, John-street, Adelphi, London, W.C., by Major G. W. C. Kaye, D.Sc. The subject will be X Rays and their Industrial Applications.

HARVEIAN SOCIETY.—The next meeting will be held on Thursday, March 17th, at 8.30 P.M., at the Town Hall, Paddington Green, London, W., when the Harveian lecture on the Thymus Gland in Everyday Life will be delivered by Dr. Leonard Williams.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—A conference convened by the Medical Officers of Schools Association will be held on Friday, March 18th, at 4.30 P.M., at the rooms of the Medical Society, 11, Chandos-street, Cavendish-square, London, W., on Punishments in the Schools.

HUNTERIAN SOCIETY.—The next meeting of this society will be held at Sion College, Embankment, London, E.C., on Wednesday, March 9th, at 9 P.M. Papers will be read by Mr. H. Tyrrell Gray on Obscure Intestinal Colic, and by Dr. A. R. Friel on the Use of the Continuous Electric Current in Treatment. All members of the medical profession are invited to attend.

AT a meeting of the Central Council of the Combined Universities Conservative and Unionist Association Mr. Sidney C. Lawrence, M.B., Ch.B. Birm., medical officer of health for Edmonton, was adopted as one of the prospective candidates for the Combined English University Constituency at the next General Election.

A MEMORIAL TO SIR HERMANN WEBER.—A tract of land near Woldingham, on the Surrey Downs, has been presented to the National Trust for public enjoyment in memory of the late Sir Hermann Weber by one of his daughters. The gift is specially appropriate, inasmuch as Sir Hermann Weber was himself a great walker and a "lover of fresh breezes and wide horizons," and this epitaph is inscribed on a seat of marble and teak placed in the woods.

PRINCESS ALICE MEMORIAL HOSPITAL, EASTBOURNE.—The annual report of this hospital for 1920 shows a deficit of nearly £5000. Notwithstanding 146 more patients than in the previous year, the annual subscriptions marked a decrease of £225, and a committee was appointed to go into the finances of the institution. The question of adopting a scheme for paying patients will probably be considered.

BRIGHTON PROVIDENT SCHEME.—Amongst the nine Brighton hospitals coöperating in the provident scheme for hospital benefits and additional medical services, propounded by Dr. Gordon Dill, is the Royal Alexandra Hospital for Sick Children. Speaking at the annual meeting of the governors of this institution on Feb. 21st Mr. R. P. Modera, chairman of the hospital, said the provident scheme in theory was ideal, but it was not yet certain how it would work in practice. It was in the nature of an insurance, and much would depend upon how it was taken up by the public. The committee, he said, were at first inclined to keep out of the scheme, which bristled with all sorts of difficulties; but since the whole future of voluntary hospitals was in a very dangerous position, the committee thought they ought to fall in line with all the hospitals in the town and give it a trial; they would treat it purely as an experiment. Mr. Modera said the hospital was also falling into line with the other institutions in Brighton in asking those responsible for in-patients to contribute what they could towards the cost of their maintenance while in the institution. That, he thought, was only fair, and involved no hardship. The doors of the hospital would never be closed to the needy poor. Where real poverty or hardship existed the cases would be admitted free, and if it was justifiable in other cases the minimum contribution of 7*s.* a week would be reduced.

Dr. Gordon Dill explained his scheme at a Brighton and Hove Rotary Club gathering on Feb. 23rd. He quoted figures showing that the cost of the maintenance of the nine coöperating hospitals was £52,000 a year, and that if the insured people in Brighton, Hove, and Preston alone became members of the scheme (£1 a year in the case of single ersons; £1 10*s.* in the case of married couples; £2 for ilies, however large) they would provide an income more n equal to that sum.

EASTBOURNE EYE HOSPITAL.—The governors of the Eastbourne Eye Infirmary at their annual meeting on Feb. 22nd decided that the institution should henceforth be known as the Eastbourne Eye Hospital. Efforts are being made to find more suitable and commodious premises. New patients during the year 1920 numbered 702, and the in-patients numbered 30.

ROYAL SUSSEX COUNTY HOSPITAL.—On Jan. 3rd last there came into operation at the Royal Sussex County Hospital, Brighton, a scale of charges for both in-patients and out-patients towards their cost of treatment and maintenance. According to the chairman of the governors, Mr. C. R. Scrase Dickins, the response has been most gratifying. At the annual court of governors on Feb. 24th he said they had met with great willingness on the part of the patients, and that at the present time they were getting from that source alone no less than £50 a week. Much satisfaction was expressed that, thanks in the main to special efforts on behalf of the hospital, a debit balance of £6000 had been converted into a credit balance of £17,000. A feature of the year's operations at the hospital was the increase in the number of massage cases, these cases marking an increase of no fewer than 6969. X ray cases increased by 1185, nearly double the number treated last year by this means.

THE RECENT OUTBREAK OF SMALL-POX IN BRISTOL.—Dr. D. S. Davies, M.O.H. for Bristol, has issued a report on this outbreak, which has been traced to a mild attack contracted in December by a dock labourer, aged 29. He had been vaccinated in infancy (four marks); the attack was so mild that he continued work except for four days discharging cargoes on three ships at Avonmouth. Dr. Davies considers it probable that he contracted his attack from infected articles, as one of the vessels came from a Roumanian infected port. On Jan. 22nd a medical examination had revealed the presence under the thick skin of the sole of one undoubted deep-seated pustule. So far as is known, he communicated the disease only to intimate bedroom contacts: (1) His wife, aged 28, vaccinated in infancy, four good scars, sickened on Jan. 2nd, developed modified discrete eruption on Jan. 4th. Secondary fever. (2) His son, 5 months, unvaccinated, sickened on Jan. 2nd, eruption on Jan. 4th. Attack semi-confluent, becoming hæmorrhagic in pustular stage, died on Jan. 12th. Another vaccinated child of 2, though equally exposed remained well. The cases were not recognised and notified until Jan. 8th, when 11 visitors had had access to the house. Of these, four sickened and are now convalescent. The last case was removed to hospital on Jan. 18th, and no further cases have occurred.

CENTRAL COUNCIL FOR DISTRICT NURSING IN LONDON.—The annual meeting was held on Feb. 28th in the Board Room, Metropolitan Asylums Board, Victoria Embankment. The report of the Executive Committee chronicled the election of Mr. E. B. Turner as chairman and Dr. Scott Lidgett as vice-chairman of the committee. The inclusion amongst the patients visited of those who were unable to employ a private nurse, rather on account of lack of accommodation than from inability to pay the cost, had been considered by the Executive Council, and a memorandum suggesting the terms on which such visits might be arranged had been circulated (THE LANCET, 1920, p. 1180). The panel of emergency nurses, instituted in accordance with resolutions of the Council on Feb. 26th, 1918, and Feb. 26th, 1920, had proved to be of considerable usefulness to the various associations. The City Parochial Foundation had renewed their grant of £100 for the training of four district nurses as midwives. The Executive Council had been approached by the National Association for the Prevention of Tuberculosis and by the Lock Hospital in regard to the need for special training for district nurses, and had therefore decided to give special consideration to the question of the district training provided and required by the associations over and above the three years' training in hospital. The Council considered that the attention of the training schools for nurses should be drawn to the large amount of additional instruction needed before a fully trained nurse was equipped for district work, and recommended that the foregoing be communicated to the General Nursing Council for consideration in connexion with the training of nurses. On the question of salaries the Council recommended that it be a condition of a grant from the Council that the minimum salary of a resident nurse shall be not less than £63 clear, and of a non-resident nurse not less than £63 clear, over and above a reasonable allowance for board and lodging. Acknowledgment was made of grants and donations received, and a statement made of the amounts allotted to various district associations, and in view of the continually increasing cost of the nursing services it was resolved that the need for and desirability of appeal to the public for funds in aid of district nursing in London should be given consideration.

PROPRIETARY MEDICINES BILL.—Dr. Addison has stated his intention to reintroduce this Bill in a modified form during the present Parliamentary session.

LONDON HOSPITAL AND INSURANCE PATIENTS.—At a meeting of the Governors of the hospital, on March 2nd, Lord Knutsford announced the decision to discontinue treatment of insured persons unless their Approved Societies came to the financial aid of the hospital. This, he believed, they would agree to do in the near future.

INDUSTRIAL WELFARE.—The Duke of York attended the Industrial Conference held at the Mansion House, London, on March 2nd, in support of the industrial welfare movement. In a letter issued to the press the Duke of York speaks of this movement as one of the most valuable contributions toward the bringing about of understanding and harmony in industry.

THE Brighton Corporation on Feb. 24th decided to place the Royal Pavilion buildings at the disposal of the Balneological and Climatological Section of the Royal Society of Medicine for its annual meeting this summer. It was also decided to give facilities for the members to visit places of interest under the control of the corporation.

NORTHERN HOSPITAL, MANCHESTER.—In spite of applying £2100 of invested funds and treating as income £650 received from legacies, the Manchester Northern Hospital for Women and Children started the past year with a debt of £1600. A bazaar held last November realised £3000, and a gift of £2800 from the National Relief Fund leaves a balance in hand of £3700. This apparent prosperity is misleading, as last year was abnormal, and the fact remains that the dependable income fell short of the expenditure of £8180 by £2320.

Appointments.

HUTT, C. W., M.A., M.D. Camb., D.P.H. Oxf., has been appointed Medical Officer of Health to the Borough of Holborn.

Certifying Surgeons under the Factory and Workshops Acts: McDOUGALL, D., M.B., Ch.B. Glasg. (Kilbride); ROBERTSON, I. M., M.B., Ch.B. Glasg. (Strichen); PEARSON, R. W., M.B. Durh. (Arundel).

Vacancies.

For further information refer to the advertisement columns.

Beckenham Education Committee—Dental O. £500.

Birmingham and Midland Homœopathic Hospital.—Res. H.S. £125.

Bootle County Borough.—Tuberc. O. and Deputy M.O.H. £750.

Bristol Education Committee.—Asst. Sch. M.O. £600.

Bristol General Hospital.—H.P.'s, H.S.'s, Cas. H.S. and Obstet. O. £175.

Bristol Royal Infirmary.—Hon. Registrar and Hon. Surg.

Charing Cross Hospital, Agar-street, W.C.—Surg. Registrar. £150.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £100.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £200.

Dunrossness Parish.—M.O. and Vaccinator. £40.

Ealing Borough.—Asst. M.O.H. £500.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsth. £50. Also Ophth. S.

East Sussex County Mental Hospital, Hellingly.—Sec. Asst. M.O. and Path. £450.

Eastern Dispensary, Leman-street, E.—P. and Ophth. S.

Evelina Hospital for Children, Southwark, S.E.—H.P. £160.

General Lying-in Hospital, York-road, Lambeth, S.E.—Res. M.O. £100.

Glamorgan County Asylum, Bridgend.—Jun. Asst. M.O. £415.

Great Northern Central Hospital, Holloway, N.—Two H.P.'s. £150.

Greenwich, "Dreadnought" Hospital.—H.S. £150.

Herefordshire General Hospital.—H.S. £200.

Laboratories of Pathology and Public Health, 6, Harley-street.—Asst. Path. £450.

Leicester Royal Infirmary.—H.P. £200.

Lewisham Hospital.—Consulting S. and Consulting P. £150. Sen. Asst. M.O. £500. Two Res. Asst. M.O.'s. £400.

Liverpool, David Lewis Northern Hospital.—Two H.P.'s. Three H.S.'s. £120.

Liverpool Royal Children's Hospital, Myrtle-street.—Two Res. H.P.'s and Two Res. H.S.'s. £90.

Liverpool Royal Infirmary.—H.P.'s., H.S.'s., and Sen. Cas. O. £60 each.

Liverpool, Royal Southern Hospital.—Two H.P.'s and three H.S.'s. £100 each.

London County Council, Hammersmith School Treatment Centre.—Eye S., Minor Ailment S., Ear and Throat S., Two Anæsth.'s. £80 each. Two Dental S.'s. £65.

London Missionary Society.—Surg., and P. and S. for Hospital Service, China.

Maidstone, Kent County Mental Hospital.—Asst. M.O. £350.

Maldon Union.—M.O. and Public Vaccinator. £107.

Manchester Royal Infirmary, Central Branch, Roby-street, Manchester.—Asst. M.O. £100.

Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Female S. £200

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Gynæc., and Dent. S.

Muktesar, India, Imperial Bacteriological (Veterinary) Laboratory.—Director and First Bacteriologist. Rs. 1500 per mensem. Also Second Bacteriologist and Pathologist. Rs. 600 per mensem each.

Newark Hospital and Dispensary.—Res. H.S. £200.

Newport, Mon., Royal Gwent Hospital.—H.S. £200.

Nottingham City Asylum.—Sec. Asst. M.O. £400.

Nottingham General Hospital.—H.S. £200.

Oldham Royal Infirmary.—Third H.S. £200.

Poplar Hospital for Accidents, Poplar.—Asst. Res. S. £150.

Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Asst. Res. M.O. £60. Also Dist. Res. M.O. £80.

Queen Mary's Hospital for the East End, Stratford, E.—H.S. and H.P. £150 each.

Rochester, Kent, St. Bartholomew's Hospital.—Jun. Res. M.O. £200.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—Hon. Anæsth. £1 1s. per attendance.

St. Bartholomew's Hospital Medical School.—Chair of Anatomy. £900.

Salford Royal Hospital.—Res. Surg. O. £250. H.P. £200. H.S.'s, Orthop. Dept. and Genito-Urinary Dept. £150 each. Cas. H.S. £150. Anæsthetist. £50.

Salisbury General Infirmary.—H.S. £200.

Samoan Medical Service.—Three Jun. M.O.'s. £600.

Sheffield Royal Hospital.—Asst. Cas. O. £150.

Sheffield Royal Infirmary.—H.S. £150 Ophth. H.S. £150. Asst. Cas. O. £150.

South Shields, Ingham Infirmary and South Shields and Westoe Dispensary.—Sen. H.S. £225.

Sunderland Royal Infirmary.—Jun. H.S. £200.

Tunbridge Wells General Hospital.—H.S. £160.

Tyne Port Sanitary Authority.—Asst. M.O.H. £750.

Wakefield, West Riding Asylum.—Jun. Asst. M.O. £400.

Western General Dispensary, Marylebone-road, N.W.—Asst. Hon. Aural S.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Non-Res. H.S. £150.

West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. £50. Also Asst. Anæsth.

West Riding County Council.—Asst. M.O. at Cardigan Sanatorium, Carr Gate, near Wakefield. £500.

Wigan County Borough.—M.O.H. £850.

Wigan Infirmary.—Hon. P. and Asst. Hon. P.

Wilts County Council.—Female Asst. County M.O.H. and Asst. Sch. Med. Inspec. £500.

Winchester, Royal Hampshire County Hospital.—Hon. Physician in Ordinary.

Wolverhampton and Staffordshire General Hospital.—Hon. Specialist Ear, Nose, and Throat Dept. Also Res. Cas. S. £300.

York Dispensary.—Res. M.O. £250.

York Retreat.—Med. Supt. £800–£1000.

THE Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for the Sheriffdom of the Lothians and Peebles. Applications for the post should be addressed to the Private Secretary, Scottish Office, Whitehall, S.W. 1, and should reach him not later than March 16th, 1921.

THE Chief Inspector of Factories announces the following vacant appointments:—*Barton-on-Humber* (Lincoln), Brading (Isle of Wight), Bromyard (Hereford), Wincanton (Somerset).

Births, Marriages, and Deaths.

BIRTHS.

COOPER.—On Feb. 23rd, the wife of Dr. R. M. Le Hunte Cooper, of Strathray-gardens, Eton-avenue, N.W., and Wimpole-street, W., of a daughter.

SCOTT.—On Feb. 21st, the wife of Eric A. Scott, M.R.C.S., L.R.C.P., 9, Harley-street, W., of a daughter.

SPENCER.—On Feb. 22nd, at a nursing home, Oxford, the wife of Gordon Winstanley Spencer, M.D., Mesopotamian Health Service, of a daughter.

MARRIAGES.

RYGATE—BEVEN.—On Feb. 26th, at Durrington Church, Salisbury, Captain J. R. Rygate, R.A.M.C., to Kathleen, daughter of the Rev. Sydney Beven, Brighton.

THE marriage arranged between Major H. Graeme Anderson, M.B.E., M.D., F.R.C.S., Surgical Consultant to the Royal Air Force, of 75, Harley-street, W., and Gladys, elder daughter of Charles Hood, of Hatch End, Middlesex, will take place on March 18th, at St. Columba's (Church of Scotland), Pont-street, S.W., at noon.

DEATHS.

ABRAHAM.—On Feb. 23rd, at Marlborough-hill, St. John's Wood, N.W., Phineas Simon Abraham, M.D., F.R.C.S.I., &c., late of Harley-street, W., aged 74.

CAMERON.—On Feb. 27th, at Dublin, Sir Charles Alexander Cameron, C.B., M.D.R.U.I., F.R.C.P.I., F.R.C.S.I., D.P.H., in his 91st year.

LOMAS.—On Feb. 24th, at Pencaitland, Ernest Courtney Lomas, C.B., D.S.O., F.R.C.S. Edin., Surgeon-Captain, R.N. (retired), aged 56.

MOSSE.—On Feb. 25th, at Belvedere-terrace, Weymouth, Charles George Drummond Mosse, Lieutenant-Colonel (retired), R.A.M.C., F.R.C.S.I., and Ministry of Pensions, aged 63 years.

SEMON.—On March 1st, at *Rignalls, Great Missenden, Bucks*, Sir Felix Semon, K.C.V.O., M.D., F.R.C.P., aged 71.

TURNER.—Feb. 28th, at Oundle, Emma Beatrice, wife of Dr. R. B. Turner, Oundle, Northants.

WRENCH.—On Feb. 23rd, at Ireshopeburn, Wearhead, Co. Durham, Edward Branson Wrench, M.B., M.V.O., F.R.C.S., of Park Lodge, Baslow, Derbyshire, in his 57th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, March 8th.

SECTION OF PSYCHIATRY: at 5.30 P.M. (instead of 8.30 P.M.)

Paper:

Dr. Henry Devine: Study of Hallucinations in a Case of Schizophrenia.

Thursday, March 10th.

SECTION OF BALNEOLOGY AND CLIMATOLOGY: at 5.30 P.M.

Discussion:

On "The Place of Baths and Health Resorts in Gynæcology."

Members of the Section, with guests, will dine together at the Welbeck Palace Hotel, Welbeck-street, W., at 7 P.M. Those intending to be present are requested to send their names to Dr. C. F. Sonntag, 80A, Belsize Park-gardens, N.W. 3, not later than the last post on March 10th.

OBSTETRICS AND GYNÆCOLOGY: Members of this Section are cordially invited to attend this meeting.

Thursday, March 10th, and Friday, March 11th.

SECTION OF NEUROLOGY } at 8.30 P.M. (Cases on
SECTION OF OPHTHALMOLOGY } March 10th at 8 P.M.)

Discussion:

On "Ocular Palsies," to be opened by Dr. Gordon Holmes and Mr. Leslie Paton, and continued by Mr. J. B. Lawford, Mr. M. S. Mayou, Mr. N. Bishop Harman, Mr. Foster Moore, Mr. W. H. McMullen, Mr. M. L. Hine, Dr. S. A. K. Wilson, and others.

Friday, March 11th.

CLINICAL SECTION: at 5.30 P.M. (Cases at 5 P.M.)

Exhibition of Cases.

Will Members wishing to exhibit cases please notify Mr. R. P. Rowlands, 12, Queen Anne-street, W. 1.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 7th.—9 P.M., Lettsomian Lecture (III.):—Mr. G. E. Gask: Surgery of the Chest and Pleura.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

MONDAY, March 7th.—8 P.M., Cantor Lecture:—Major G. W. C. Kaye: X Rays and their Industrial Applications. (I.)

HUNTERIAN SOCIETY, at Sion College, Embankment, E.C.

WEDNESDAY, March 9th.—9 P.M., Papers:—Mr. H. T. Gray: Obscure Intestinal Colic.—Dr. A. R. Friel: The Use of the Continuous Electric Current in Treatment.

BIRMINGHAM MEDICAL PSYCHOLOGICAL SOCIETY.

WEDNESDAY, March 9th.—4.15 P.M., Paper:—Dr. G. Gordon: Amnesia.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

There will be Daily Demonstrations in the Wards and Out-patient Department by the Staff of the West London Hospital at 10, 11 A.M., and 12 noon, and 2 P.M. All the Special Departments of the Hospital will be used for teaching purposes. The following lectures will be delivered during the week:—

MONDAY, March 7th.—5 P.M., Dr. G. Stewart: Spinal Tumours.

TUESDAY.—5 P.M., Dr. Pernet: The Alimentary Tract and Morbid Skin Manifestations.

WEDNESDAY.—5 P.M., Mr. Gibb: Glaucoma.

THURSDAY.—5 P.M., Dr. B. Spilsbury: Arsenical Poisoning.

FRIDAY.—5 P.M., Mr. Steadman: Dental Sepsis in Relation to the Alimentary Tract.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, March 7th.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Mr. Scott: Disturbances of the Vestibular System. (II.)

TUESDAY, March 8th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Risien Russell: Syphilis of the Nervous System. (I.)

THURSDAY, March 10th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Dr. Gordon Holmes: Muscular Atrophies. (II.)

FRIDAY, March 11th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Russell J. Reynolds: X Ray Demonstrations of Cases.

Fee for Post-Graduate Course £7 7s. C. M. HINDS HOWELL, Dean

MIDDLESEX HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

TUESDAY, March 8th.—3 P.M., Emeritus Lectures:—Dr. W. McC. Wanklyn: The Future of the Medical Profession.

THURSDAY.—3 P.M., Emeritus Lecture:—Sir Alfred Pearce Gould: Surgery, a Progressive Science: the Latest Word is not the Last Word.

FRIDAY.—3 P.M., Sir James Kingston Fowler: The Treatment of Tuberculosis.

KING'S COLLEGE (DEPARTMENT OF SCIENCE), Strand.

Nine Lectures on Problems of Modern Science.

WEDNESDAY, March 9th.—5.15 P.M., Lecture (VIII.):—Prof. W. D. Halliburton: Physiology.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 10th.—4 P.M., Lecture:—Dr. C. B. Heald: Muscular Defects in Poliomyelitis.

TIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

MONDAY, March 7th.—5.30 P.M., Post-Graduate Lecture:—Dr. J. Parkinson: Dropsy.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, March 10th.—6 P.M., Chesterfield Lecture:—Dr. K. Sibley: Electrical Treatments. Diathermy and High Frequency.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, W.

TUESDAY, March 8th.—3 P.M., Lecture:—Prof. A. Keith: Darwin's Theory of Man's Origin.

THURSDAY.—3 P.M., Dr. G. C. Simpson: Meteorology of the Antarctic.

FRIDAY.—9 P.M., Dr. J. Freeman: Medical Idiosyncrasies.

SATURDAY.—3 P.M., Lecture (II.): Sir Ernest Rutherford: Electricity and Matter.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, March 8th.—4.30 P.M., Lecture:—Mr. H. H. Rayner: Surgical Disorders of Infancy and Early Childhood.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, March 10th.—4.30 P.M., Dr. Jenkins: The Examination of Sputum. (At Salford Royal Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, March 11th.—4.30 P.M., Dr. Ward: Dyspepsia in Infancy.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade lane.

SATURDAY, March 12th.—3.30 P.M., Dr. Chisholm: Demonstration of Food Preparations with Comments on their Therapeutic Value. (At the Babies' Hospital.)

Communications, Letters, &c., to the Editor have been received from—

WESTERN OPHTHALMIC HOSPITAL.—The monthly clinical meeting was held on Feb. 23rd, when the following cases were shown: (1) Congenital Dislocation of the Lenses in High Myopia; (2) Retinitis Pigmentosa; (3) Intramarginal Cupping of the Discs; (4) Gumma of the Iris, by Dr. Hugh Thompson; (5) Keratitis Nodosa, by Mr. Cole Marshall; (6) Intramarginal Cupping of the Discs, by Mr. W. L. Holyoak; (7) Early Choroiditis at the Macula; (8) Specific Retino-choroiditis; (9) Optic Atrophy in Tabes Dorsalis; (10) Tubercular Choroiditis; (11) Syphilitic Retino-choroiditis Resembling Retinitis Pigmentosa, by Mr. A. Rugg-Gunn. These meetings are held at 5 P.M. on the fourth Wednesday of each month, and medical practitioners and others interested are cordially invited to attend. Any further information may be obtained from Mr. A. Rugg-Gunn, secretary of the Medical Committee, 9, Wimpole-street, London, W. 1.

Notes, Short Comments, and Answers to Correspondents.

THE IMPORTANCE OF BIOLOGY.

LECTURING on Problems of Modern Science at King's College, London, on Feb. 23rd, Professor A. Dendy said that scientific knowledge of all kinds had been accumulating during the past century at an altogether unprecedented rate, and it was necessary that the heap should be organised in some rational manner. Biology had much in common with chemistry and physics, and it might be regarded as a sort of super-chemistry and super-physics, though the living organism, taken as a whole, was something more than a mere physical and chemical machine. In this fact lay the justification for separating biology from chemistry and physics and in regarding it as one of the cardinal sciences. The general divisions of biology adopted by our universities were on the whole justified, but had many disadvantages, and a strictly logical foundation could hardly be claimed for the system of classification. The anatomists and physiologists of our medical schools had been seriously handicapped by taking too narrow a view of the wide relationships of biological science.

Progress of Biological Science.

Pleading for a wider interpretation of the subject Professor Dendy suggested a scheme under the main headings of pure biology, experimental biology, philosophical biology, and applied biology, and passed in rapid review the work which would fall under the main headings and under their many subdivisions. The descriptive and systematic work which belonged to pure biology, he said, was necessary to the experimental biologist who could not carry out his investigations until he knew with what material he had to deal, while the philosophical biologist had to rely on both branches. It was in the domain of cytology that much of the most important progress in biological science had lately taken place, and its study had become a necessary adjunct to a right understanding of heredity. In this connexion the lecturer mentioned the work of Professor Morgan and his colleagues in America in regard to the chromosomes, and maintained that a knowledge of embryology must still be regarded as an indispensable part of the equipment of the student of comparative anatomy and organic evolution. This was still more true of palæontology, in which great advances had been made in recent years, and, whether with Huxley we derived the human stock from some ape-like form or, with Wood Jones, placed it further back, it made no difference to the belief that man was one final product in one direction of organic evolution. We could safely trust the labours of the palæontologist to fill in more completely the gaps in our knowledge. Reverting to the work of the systematologist the lecturer said that not only now, but still more in the future, there would be urgent need of some kind of museum training as well as for international coöperation.

Biology and Medicine.

Experimental biology opened up a vast field and some of the individual problems involved would be sufficient to occupy a man during his lifetime. Physiology had long been recognised as of primary importance in the university curriculum, and although regarded as a distinct science it clearly overlapped almost every other department of biology. It was a vast subject which required subdivision before it could be adequately treated. General physiology of plants and animals dealt with the complete vital activities of individuals, and biochemistry and biophysics formed the connecting links with the sister sciences, bringing the living organisms into contact, so to speak, with the inanimate world. Physiology of the special functions in any scheme would probably have to receive special treatment. Experimental psychology, including what was commonly called the behaviour of animals, was a branch of physiology at present much studied and was the chief field of contest between the mechanist and the vitalist. The study of animal behaviour merged almost imperceptibly into experimental morphology and embryology. Heredity concerned itself with the unravellings of the connexions which exist between parent and offspring, and the studies of Mendel had been fruitful in results of practical importance. The Mendelian factors whose existence had been demonstrated by the genetist had not yet been identified as entities in the germ cells, but the American school had localised them with great probability in the chromosomes. The truth appeared to be that the Mendelian factors were only modifying agents. There were probably no special factors, for example, that determined whether the normal human being should have a nose or no nose, though they might decide whether the nose should be of one shape or another, just as there were factors which determined the colour of the eyes. The so-called Mendelian factors which modified organisms might be of a chemical nature, since a perfectly definite result was got from a perfectly definite stimulus. Investigations in the study of the blood had developed almost into a new science which was really a part of biochemistry and biophysics. An injection of the spermatozoa of one animal into the blood stream of another animal of a distinct species produced in the blood an antibody which caused the destruction of foreign bodies. By injecting a solution of the lens from the eye of a rabbit into the blood of fowls a lens-sensitised serum was produced capable of dissolving lens tissue. This serum injected into pregnant rabbits produced animals with defective lenses, and this defect was inherited by at least six generations. Moreover, it had been shown that the effect could be produced through the male rabbit alone.

In conclusion, Professor Dendy said that the question as to how far applied science should form part of the University curriculum was a matter for discussion, but everyone would agree that both pure and applied biology must remain in touch with each other. Medicine, surgery, parasitology, and other sciences were dependent upon biology, and pure science must be regarded as the root and applied science as the fruit of the tree. If the root were starved the crop of fruit would not be forthcoming.

FISHERMEN'S DISEASES.

AT a recent meeting of the Norfolk and Norwich Medico-Chirurgical Society, held at the Norfolk and Norwich Hospital, Dr. H. Muir Evans had much of interest to say on injuries and diseases peculiar to fishermen. Lantern slides showed the general appearance of several poisonous fishes, including the dog-fish, the sting ray, and the greater and lesser weever; also the microscopical features of the poison glands of each species from sections cut by the author and photographed by Dr. D. H. Hutchinson, of Lowestoft.

The injuries produced by the prick or sting of fish armed with spines are usually, Dr. Evans said, the result of an unpremeditated contact with the greater or the lesser weever, which possesses a perfect double-grooved exploring needle on either gill cover. Each grooved spine is covered by a movable skin. At the root of the spine is a definite poison gland, and when alarmed the fish erects its gill cover and bends itself round, driving the poisoned spine into any adjacent body, which at once receives some grumous drops of a highly poisonous nature. There are lesser poison organs in each spine of the dorsal fin. The burning pain that ensues is so great that men will attempt to throw themselves overboard, or will hammer the affected part with a thole pin against the bulwarks. The pain lasts several hours and is associated with immediate swelling of the affected limb; a certain amount of paralysis may affect the limb temporarily. The swelling subsides in a few hours or may go on to phlegmonous inflammation with local gangrene around the site of injury.

The Nature of Fish Venom.

The study of snake venoms has shown the presence of different toxins, one acting on nerve tissues, a neurotoxin, another on red blood cells, a hæmolysin, another on white blood cells, a leucotoxin, and another on the epithelial lining of blood-vessels. It is possible to fix a neurotoxin to nerve cells in vitro, the hæmolysin remaining in solution, and vice versa. Weever venom contains a neurotoxin, a hæmolysin, and a leucotoxin. The hæmolytic constituent of weever venom differs, however, from most snake venoms in that it acts directly on washed red corpuscles—that is to say, without the presence of serum. This statement conflicts with that of certain French workers, but my experiments were made with fresh poison, whereas they made use of filtered glycerine extracts. The French view is that venoms can only cause solution of blood cells in the presence of a heated serum, while a normal serum inhibits the action. To complete the analogy between this and other venoms, Briot has been able to immunise dogs and rabbits by repeated local injections of the venom, so as to render them insusceptible to many times the lethal dose of poison injected intravenously. As early as 1879 Bottard recorded an experiment in which he had injected a dog with the venom, and after the slough thus produced had separated, 16 days later, he put some drops of the venom into the eye of the same dog without producing any effect.

Experiments I have made on the paralytic effect of the venom on white blood corpuscles show a marked diminution in the phagocytic action of the leucocytes. Secondary septic inflammations frequently follow the sting of these fish, a result which shows how readily the barrier of phagocytosis may be broken down to admit pathogenic organisms from the dirty skin.

Treatment of Fish "Sting."

The various empirical methods of treatment are worthy of study. For example, the injury being called a sting, on analogy with the acid ant's sting ammonia is presumed to counteract the poison. In the islands of Mauritius and Réunion, where a similar stinging fish, the Synancia, frequently injures the feet of fishermen, the natives employ the leaves and seeds of a species of Datura which grows in abundance on the dry sand of the shore, and find it gives relief, in the same way as a person stung by a nettle flies to a dock-leaf. But among the plants employed in an empirical way to cure the prick made by the fish the seed of *Abrus precatorius* seems, according to Bottard, to have the virtue of a specific. We are familiar with abrus or jequirity seeds as a remedy for certain chronic eye diseases, while a toxin abrin derived from it has been shown to possess the characters of the toxins of diphtheria and tetanus, dissolving red blood cells and possessing also a neurotoxic effect. Test-tube experiments show that abrus has an inhibiting effect on hæmolysis by weever venom.

Of local methods of treatment the most frequent is to plunge the part into boiling vinegar; another is to hold the limb over the funnel of the boiler which, in a smack, drives the donkey engine. A third is to apply heat vicariously by throwing the offending weever on the fire. Sometimes the sufferer soaks a piece of brown paper in vinegar, allows it to dry, and, wrapping the paper round the finger, applies a light, letting the paper smoulder until the heat becomes unbearable. Another treatment consists in cutting out the fish's liver and applying it to the wound. Here we are again approaching scientific method. Serpent's bile appears to be an antidote to serpent's venom, and a preparation of snake's liver is of value in the treatment, not only of snake-bite, but also of some disease toxins, as of tetanus and diphtheria. Possibly the effect of the liver is due to cholesterin. Cases of tetanus have been successfully treated with injections of cholesterin, and it has been established that cholesterin inhibits hæmolysis by cobra venom (Preston Keyes) and arachnolysin.

As with snake venoms, potassium permanganate, chloride of lime, and chloride of gold destroy the venom rapidly, and I have suggested that all smacks and drifters should be provided with a Lauder Brunton snake-bite lancet (which at one end contains pot. permang. crystals), so that a really efficient remedy may be at hand.

Jelly-fish Stings and Water Boils.

In the summer voyages the drift fishermen get their nets full of jelly-fish, and the sting frequently causes burning pain followed the next day by intense itching. From the tentacles of actiniæ a toxin has been isolated, thalassine, soluble in water and alcohol but insoluble in ether, which produces intense itching. The eyes and nose of those mending the dry nets after summer fishing are often affected, and this is, so far as I know, not described in any work. It would seem as if the dry toxin of the jelly-fish becomes mixed with the dust from the nets, so that the fishermen are frequently unable to mend the nets on account of the sneezing and lacrymation which the handling of them produces. It would be interesting to collect the dust from these nets and extract the toxin which they no doubt contain.

Finally, I must mention water boils, occurring on the forearm of fishermen and sometimes extending up to the elbow, but mostly to be found over the lower ends of the radial and ulnar borders of the arm. These boils begin as pustules, but may extend and form large suppurating areas of half to one inch in diameter. No doubt they are connected with the rubbing of the edge of their oilies, wet with sea-water and all the dirt of the fisherman's calling. They are most frequent in the autumn and winter. They cause many weeks' incapacity to the men, when they say their blood is out of order. I have examined the pus from these boils and find it in all cases to give a pure culture of *S. pyogenes aureus*. In severe cases I have given injections of vaccine with good results. The prevention of infection from one fisherman to another is also important.

SIR ASTLEY COOPER.

To the Editor of THE LANCET.

SIR,—You have recently published a justly laudatory article upon Sir Astley Cooper. It comes as a surprise, therefore, to find the following paragraph in Samuel Smiles's "Life of George Stephenson," the celebrated engineer, when he was engaged in constructing the London and Birmingham Railway: "Sir Astley Cooper, the eminent surgeon, near whose estate at Hemel Hempstead the railway would pass, was one of the most active opponents to the measure, and a deputation of the directors one day called upon him for the purpose of mitigating his opposition. They found a courtly old gentleman, of highly dignified manners and appearance. The deputation explained to him their project and he politely heard them out: but Sir Astley was not to be conciliated. 'The scheme is preposterous and absurd,' said he, 'from beginning to end. You are entering upon an enormous undertaking of which you know nothing. Then proposing to destroy property, cutting up our estates in all directions! Why, gentlemen, if this sort of thing be permitted to go on, you will, in a very few years, destroy the *noblesse!*' The deputation retired disgusted, one of them bitterly remarking after they had left—'Well it is really provoking to find one who was made a "Sir" for cutting a wen out of George IV.'s neck charging us with destroying the noblesse because we propose to confer upon him and his neighbourhood the benefits of a railway!'"

I am, Sir, yours faithfully,

Holland Park-avenue, Feb. 26th, 1921. S. D. CLIPPINGDALE.

A HYGIENIC TELEPHONE MOUTHPIECE.

Mr. Archibald T. Hutchinson, of 67, Burt-terrace, Gateshead-on-Tyne, has sent us a specimen of a telephone mouthpiece, which is used by the Newcastle-on-Tyne Electric Supply Company. Made of a wax-like substance impregnated with an antiseptic, it is simple in construction and takes the form of a movable lining to the fixed mouthpiece. The appliance is said to last for some two or three months before requiring renewal. The creasote-like odour of the antiseptic makes the mouthpiece pleasant to use, while there is no obstruction to the sound of the voice.

THE CONTENTS OF ARTIFICIAL PEARLS.

To the Editor of THE LANCET.

SIR,—Professor A. J. Hall last week gave an interesting case of local dermatitis apparently determined by the wearing of an artificial pearl necklace. He does not mention whether the contents of the beads were analysed. Blown pearls usually consist of globules of glass coated on the inside with the so-called oriental pearl essence, or *essence d'orient*. This is a liquor prepared from the scales of various cyprinoid and clupeoid fishes, some of which are popularly known as whitings, as the bleak, or ablette in French; the scales give the brilliant iridescence to the artificial pearls. The scales are rubbed down in a mortar with fresh water and strained. Ammonia is added to prevent decomposition and to aid in coating the pearls. The rest is white wax or alabaster, but parchment-glue, isinglass, or mucilage is also used. Sometimes hydrofluoric acid and oxide of tin are employed in preparing the glass. The *ablette* used to be plentiful in the Seine. A Frenchman named Jannin is believed to have first invented the manufacture of artificial pearls about 1680. I am, Sir, yours faithfully,

OYSTER.

"*Intestinal Disinfection.*"—The publishers of this brochure are the Universal Medical Periodicals, Ltd., of 36, Whitefriars-street, London, E.C.

The Langham Telephone Exchange.—After 2 P.M. on Saturday, March 5th, the telephone number of the office of the General Medical Council will be Langham 2500.

Common Sense.—It is no longer possible for a man to take his stand unchallenged on the position given him by belonging to "one of the three learned professions." Our correspondent's communication would lead to immediate contradiction.

An Address

ON

THE NEUROLOGICAL ASPECTS OF SHOCK.

Delivered before the Leicester Medical Society on Feb. 9th, 1921,

BY SIR FREDERICK MOTT, K.B.E., M.D. LOND., LL.D., F.R.S.

SHOCK may be defined as a condition of profound exhaustion and prostration of voluntary and involuntary functions of acute onset, caused by trauma, surgical operations, or sudden emotional or commotional disturbance of the central nervous system, or to the effects of toxic agents and anaphylaxis. The term has unfortunately been greatly extended by the inclusion of all forms of war neurosis under the name of "shell shock," the symptoms of which in no way differ from cases that have never been exposed to shell fire. It will be my endeavour to show that over-stimulation and exhaustion of the central nervous system play an important part in the production of all forms of shock.

PRIMARY AND SECONDARY SHOCK.

Two forms of shock may be recognised: (*a*) primary; (*b*) secondary.

Primary shock.—This form is analogous to a faint or collapse coming on instantaneously as a result of emotional or commotional disturbance of the brain. It may come on immediately on receipt of an injury, but in some instances when the patient actually sees the injury, showing that the emotional disturbance was the cause and not the injury.

Secondary shock.—The late onset of secondary wound shock does not refute the theory that surgical shock may be the result of over stimulation by nociceptor afferent impulses *exhausting the vital medullary centres presiding over the* circulation and respiration; but it allows of the conception that other factors—namely, the *toxic*—play an important part in its causation, for in secondary shock the necessary time for the production and absorption of toxins would occur.

Before passing on to discuss the two forms of primary and secondary surgical shock it is necessary to make a few remarks upon anaphylactic shock.

Anaphylactic Shock.

Prior to the discovery of anaphylactic shock by Richet it was the fashion to ascribe all the "shock" effects of the ingestion of harmful substances into the body to toxæmia. Anaphylactic shock is characterised by dyspnœa, fall of blood pressure, vomiting, and other gastric intestinal disturbances, accompanied by collapse, and in some cases by convulsions, a symptom-complex which follows the administration of any one of a large number of dissimilar substances of animal or mineral origin to which the blood and tissues is inherently over-sensitive, or has been rendered over-sensitive by previous administration.

These symptoms, according to Widal and his collaborators, are accompanied and preceded by a "blood crisis" of remarkable suddenness and intensity characterised by a leucopenia with predominance of lymphocytes, diminution of blood platelets, and great alteration in coagulability. They propose to call this condition hæmoclasia, the term implying a sudden dislocation of the static equilibrium of the colloids of the blood—a bio-physical manifestation—and this was the conclusion arrived at by Bezredka in 1907. But the physics and chemistry of the colloids, about which at present we know but little, underlie all vital phenomena, and it may be presumed that in anaphylactic shock there is a dislocation of the static equilibrium of all the cells of the body, especially of the nervous system, and the term colloidoclasia would more accurately represent the condition. Idiosyncrasy may be regarded as a specialised inherent hypersensitiveness to the dislocation of the static colloidal equilibrium from the action in the body of particular substances.

THE FALL OF BLOOD PRESSURE IN ALL FORMS OF SHOCK.

In all forms of shock there is a fall of the blood pressure, and when death takes place it is by a failure of the vital autonomine centres presiding over the circulation and respiration. Now, in shock, which comes on some time after injury, this question arises: Do these vital centres fail to function, primarily on account of exhaustion through over-stimulation, or do they fail secondarily from (1) the effects of toxins, (2) from fall of blood pressure and consequent anæmia, or (3) from exæmia with concentration of blood and capillary stasis in some cases accompanied by fat embolism?

In my opinion there is evidence to show that in secondary shock from extensive burns and severe wounds, especially compound comminuted fractures with extensive laceration and injury of the soft parts, all the before-mentioned factors conspire together to form a vicious circle, which tends to a fatal termination by failure of the vital autonomic centres presiding over circulation and respiration. In fatal primary emotional or commotional shock toxin absorption cannot play a part, for the symptoms immediately follow the exciting cause; and a fatal termination can therefore only be due to a refractory or exhausted condition of the vital autonomic centres presiding over the circulation and respiration.

PRIMARY SHOCK AND THE PSYCHONEUROSES.

What is the psycho-physiological explanation of emotional shock? We know that a sudden emotion may cause a "faint," a sudden loss of consciousness explicable by a sudden fall of blood pressure. Now, if the fear stimulus which caused this persists there may be a continuance of arrest of function of the autonomic centres; and in very rare cases a fatal termination has been known to result. Individuals who are inherently neurotic or of a timorous temperament, or persons whose higher controlling centres have been exhausted by prolonged stress, anxiety, and insomnia, are most susceptible to emotional shock.

In the great majority of cases of primary commotional and emotional shock after a variable time the patient recovers. In hysterical patients some part of the field of consciousness may remain dissociated, and the result is mutism, psychic blindness or deafness, paralysis, tics, tremors, contractures, &c., all of which can be readily cured by suggestion or persuasion. Not infrequently following the emotional shock the patient remains for a time in a dazed or semi-automatic state. He has no recollection of what transpired during this period of his life. It may happen that he does not recollect the events which immediately preceded the shock; and I have seen cases in which the shock was so severe that the memory of all past events of their life were blotted out, and in several cases of this kind they spoke only a few simple words in an infantile way, both as regards the words used, the mode of articulation, and the modulation of the voice.

Now, two types of psychoneurosis may follow emotional or commotional shock—viz., hysteria and neurasthenia; the former was the commoner in the ranks, the latter much the commonest in officers. Hysterical symptoms arising from auto- or hetero-suggestion were curable by contra-suggestion. They were the result of a preservation of an unconscious wish-fulfilment to avoid an intolerable situation; a defence mechanism related to the emotion of fear. The other form of psychoneurosis, which may follow emotional or commotional shock, is neurasthenia—irritable nervous weakness with mental preoccupation, concerning a situation for which the man is unable to make fitting necessary mental adjustment. In the case of officers there was a continuous mental conflict between the impulse to return to duty, fearing otherwise that they would be considered either cowards or scrimshankers, and the fear of returning to an intolerable situation, not always intolerable on account of the danger to life, but intolerable because they felt they did not possess the will-power and energy to undertake efficiently duties and responsibilities involving the lives of their men. This mental conflict, combined with insomnia and unrefreshing sleep accompanied by terrifying dreams, together with the effects of previous stress and strain of war can exhaust the vital energy of a good soldier and render him more susceptible to either primary or secondary shock.

No. 5089.

Now, one of the problems medical officers in the Great War had to decide was whether a case of shock should be classified as a battle casualty. Was the patient sufficiently near a large shell when it exploded to cause commotional shock? Especially would such a classification be justifiable if the man were buried, or if the shell burst in a dug-out, or closed space, where the effects of repercussion would be felt and if he had signs of contusion on the body. Still, many individuals with an inborn or acquired emotivity might suffer so severely from emotional shock that it would be extremely difficult to decide from symptoms whether the case was commotional or emotional. For a man neuro-potentially sound, after prolonged stress, anxiety, and exhaustion of trench warfare, may become emotive. The previous conduct of the man as a soldier, the time he has been on active service at the front prior to the occurrence of the shock are important indications. If when he recovered consciousness there existed a retrograde amnesia and he exhibited neurasthenia and not hysterical symptoms it may be presumed that the case was one of commotional shock. Observations, moreover, show that in commotional shock, as distinct from purely emotional shock, the cerebro-spinal fluid exhibited an increased pressure when lumbar puncture was performed; it has also been found that the fluid upon examination contained protein and in some cases blood. True commotional shock is, relatively to emotional shock, rare, perhaps 5 to 10 per cent. of the cases of so-called "shell shock."

"COMMOTIONAL SHOCK."

The forces generated when high explosives are detonated are enormous, and men have been found dead from shock without visible injuries to account for it in dug-outs and closed spaces where percussion and repercussion can occur. Undoubtedly there is a condition of true commotional shock, although there is a tendency now almost to decry its existence. The brains of soldiers who have died of commotional shock have been sent to me to examine, and my observations show that this form of shock is a definite condition not met with in other forms of shock which I shall describe. Moreover, Colonel P. W. G. Sargent, in a very interesting introduction to an article on Shock, published by the Medical Research Council, gives instances of two cases of death from shock caused by explosives, in which the brains showed no naked-eye evidence of injury and no fracture of skull. Perhaps if the brains had been examined microscopically similar changes to those which I shall describe might have been found.

Before, however, considering the nature of the different forms of shock, let me call your attention to some anatomical and physiological facts bearing upon the subject of primary and secondary shock.

Anatomical and Physiological Facts Bearing upon Shock.

Referring to the theory of dislocation of the static equilibrium of colloids as a cause of anaphylactic shock, we may ask, may this be an explanation of commotional shock, in which no sufficient visible macroscopic or microscopic changes can be found to account for the symptoms. The study of the living neuron shows that Nissl bodies and fibrils in the ganglion cells are artefacts, the result of death changes, and due to the action of fixatives and stains; for if we look at the living nerve cell by direct illumination, we see an emulsion of black dots in the plasm, in the centre of which is the nucleus; the converse is observed in the cell when examined microscopically; for it seems to consist of a plasm in which are numbers of highly refractile granules of similar shape and size, with a dark-looking non-refractile nucleus, which contains none of these granules. When the living cells are stained with vital blue the granules take the blue stain. If the cells so stained are kept in cerebro-spinal fluid in an atmosphere of N the blue colour fades to a green. This affords evidence that the granules form an oxygen surface like spongy platinum. By the catalytic action of the P and Fe of the nucleus the molecular oxygen on the surface of the granules is continually being converted into atomic oxygen, and this process is fundamental to the life and functional activity of the neuron. Now it is conceivable that a violent commotion, even without contusion sufficient to cause minute hæmorrhages into the nervous substance, may have a ofound effect upon these delicate colloidal structures l cause a dislocation of static equilibrium. The force of the explosion may be so great as to be conveyed through the enclosing structures of the brain, and in spite of the special protective water-cushion mechanism of the cerebro-spinal fluid, cause a "shock" to the vital centres of the medulla, and sooner or later a fatal termination; the rupture of small vessels may not be sufficient of themselves to account for death, but are merely an expression of the force of the explosion.

Nissl Granules and Neural Energy in Relation to Shock.

Do we possess methods by which we can ascertain the existence of exhaustion of the neural energy of the ganglion cells and biochemical changes upon which can be established a neuropathological theory of "shock." Now, although the Nissl bodies are artefacts, yet the amount of this basic chromophil substance may be regarded as an index of the amount of stored energy substance; and to continue the argument we must assume that stimuli arriving at the cell excite the katalytic action of the nucleus and the stored latent energy substance is thereby transformed into active energy in the form of stimuli, which are transmitted directly or indirectly to muscles and glands through systems of neurons. Now it is quite obvious that excessive stimulation, when associated with multifarious depressing conditions, may lead to exhaustion by over-stimulation of this latent store of neuro-potential; and particularly is this likely to occur if there is a fall of blood pressure accompanied by other contributory factors, especially pain and loss of sleep, during which neural energy is stored. Crile's experiments show that an exhaustion of the kinetoplasm may occur from absence of sleep.

Crile's Theory of the Inter-relation of the Brain, the Thyroid, and the Adrenal Glands in Relation to Shock.

Crile maintains that there is an inter-relation of the brain, the thyroid, and the adrenal glands. He puts forward the theory that "through the special senses and common sensibility environmental stimuli reach the brain and cause it to liberate energy, which directly or indirectly activates muscles and glands, among others the thyroid and adrenals." The thyro-iodin is essential for the storage of neural energy. The clinical symptoms of myxœdema show this, and I have found in seven cases of myxœdema a great diminution of this basophil-staining substance of the neurons, especially affecting the autonomic cells of the medulla.

The work of Cannon and Elliot has shown that in anger and fear there is an increased quantity of adrenalin discharged into the circulation. The instinctive protective reaction in a struggle for life in man is either fight or flight, both of which require an increased production of energy in the whole neuro-muscular mechanism. The store of adrenalin in the suprarenal gland is a defensive mechanism for emergencies connected with the instinct of self-preservation. Not only does the substance raise the blood pressure; it stimulates oxidation processes, mobilises the glycogen in the liver as sugar, and increases the coagulability of the blood; and it also excites the discharge of thyro-iodin into the circulation. This automatic pouring out of adrenalin and thyro-iodin is brought about by an excitation of the autonomic centres in the medulla conveyed to the suprarenal glands by the splanchnic nerves. In persistent paralytic fear or persistent psychic shock there is a continued emotional refractory reflex condition of these medullary autonomic centres causing establishment of a vicious circle connected with the normal storage and discharge of neural energy. This condition is much the more likely to occur in trench warfare than in a war of action; for the soldier exhausted by prolonged stress of enforced inactivity, unable to fight or run away, the two instinctive protective reactions to threatened dangers, has to adopt the paralytic crouching attitude of concealment.

Having thus dealt briefly with the psychic mechanism of emotional shock I will pass on to a description of the morbid changes found in "commotional shock"; but it must be obvious that a man whose neural energy has been exhausted by stress and strain and has become neurasthenic is more likely to suffer severely and die from shock caused by the explosion of a large shell near him than a man whose neural energy is not in a state of exhaustion. The following case illustrates this point:—

Case of Commotional Shock and the Microscopic Findings in the Brain.

A soldier developed nervousness, owing to the severe stress of fighting on the Somme, which he never lost, but was able to control for six months. Later he was in an area which was subjected to an intense bombardment, during which, as far as can be ascertained, no gas-shells were used; this lasted about four hours. Although he remarked to another man "he could not stand it much longer," he did not give way until the following day, 12 hours later, when perhaps six shells came over. He was *not buried and not gassed*. One burst just behind his dug-out—viz., 10 feet away—in the morning, but many must have been as near the previous day. Early symptoms were general depression and tremors. The later symptoms were coarse tremors of the limbs, crying, *inability to walk or do anything*. He could not answer questions and his pupils were dilated. The condition of the pulse is not noted. The M.O. who made this report states that he was very busy with wounded at the time, and unfortunately did not make a detailed examination. He was admitted to F.A. in the evening in a state of acute mania, shouting "Keep them back." He was given two hypodermics of morphia and chloroform and slept all night. Next morning he woke up apparently well and suddenly died. It cannot be said that the clinical notes are very satisfactory, and from the correspondence it appears that there was some difficulty in obtaining them. The report of the P.M. examination by Captain Adrian Stokes is completely satisfactory. I will do no more than give his conclusion. "There was no gross lesion of the viscera, which would have been a cause of death, but though I have never seen a case of 'shell shock' I consider the condition of the brain is consistent with that diagnosis." The notes state there were no external marks of violence on the body other than some small scratches on the chest wall. The lungs were œdematous, and in the substance of the lower lobe of the left lung there was a hæmorrhage.

Head.—There was a slight bruise on the scalp in the frontal region. The brain was extremely congested, and on each side of every vessel there was an ecchymosis. There were a number of minute punctiform hæmorrhages at the termination of the smallest vessels on the surface of the brain. The whole brain was soft, but not markedly œdematous. The cerebro-spinal fluid appeared to be tinged with blood. There was no large hæmorrhage found and no small intracerebral petechiæ.

It may be remarked that hæmorrhage into the lung has been found in animals exposed to the force of detonated high explosives and a similar condition of the brain.

The main interest of this case is that there was no complication of gas poisoning; in the other two cases this cannot be excluded, and probably existed for the punctiform hæmorrhages found in the corpus callosum, and white matter is found in CO and other forms of gas poisoning due to thrombosed vessels. In the white matter of the corpus callosum, the internal capsule, the basal ganglia, the pons and medulla there are seen congested veins and hæmorrhage into the sheaths of the vessels; and in the lower part of the medulla oblongata a vessel has ruptured, not only into the sheath of the vessel but into the adjacent nervous tissue. Inasmuch as in this case death in all probability resulted from heart failure, it may be associated with the changes observed in the cells of the vagus nucleus. The macroscopic and microscopic appearances of the brain are consistent with fall of blood pressure and cerebral anæmia.

CEREBRAL ANÆMIA AND SHOCK.

I have found that certain similar conditions indicative of cerebral anæmia exist in the brains of all cases of fatal shock, whether primary, due to shell concussion, or secondary shock following cases of (1) extensive burn, (2) severe gunshot wounds with fracture of bones and much laceration of tissues, and (3) contusion of heart and slight gunshot wounds. In most instances there was a wet condition of the brain; in a few cases the superficial veins were noted as being congested at the *post mortem*. I have observed similar conditions in the brains of animals after ligation of all four vessels. They indicate a deficiency of blood in the brain, its place being taken by cerebro-spinal fluid.

MICROSCOPIC EXAMINATION OF BRAIN IN SURGICAL SHOCK.

Microscopic examination revealed in all these cases of shock (1) many empty collapsed vessels in the substance of the brain, with dilatation of the periadventitial spaces and perineuronal spaces, both of which are filled with cerebro-spinal fluid; (2) a variable degree of chromatolysis of the brain cells, most marked and obvious in the autonomic nuclei of the medulla oblongata and less marked in the bulbo-spinal motor nuclei—e.g., the hypoglossal and cervical spinal motor cells; (3) the smaller pyramidal cells of the cortex are, as a rule, more affected than the large pyramidal and Betz cells; (4) the cells of Purkinje have shown definite chromatolysis and a tendency to take the eosin-acid staining dye in place of the blue basic dye. This confirms the observations of Crile, who noted this change of staining reaction in all forms of shock, whether in human beings or as a result of experimental conditions in animals.

Why does this occur with such constancy and intensity in this organ of uniform structure? There are many biological and physiological facts in support of the view that one, and perhaps the most important, function of the cerebellum is that of a large store of neural energy for reinforcing muscular action. The acidophil reaction which Crile found that these cells manifested; he used as one argument in favour of "acidosis" in the production of shock. In the very remarkable and extensive series of researches which have been carried out under his direction, attention has been directed only to the cerebellum. Other cells of the central nervous system do not show this acidophil reaction. But that "acidosis" is an essential factor cannot be claimed for intravenous injection of alkaline. Locke or Ringer's fluid does not prevent a fatal termination in cases of shock.

Fat Embolism in Surgical Shock.

Porter examined the brains of a number of cases of surgical shock caused by extensive gunshot wounds and found fat embolism. He came to the conclusion that this might be the cause. I have found fat embolism in three cases of gunshot wound with compound comminuted fractures of large bones and much damage and laceration of the soft tissues, but I do not think it was sufficient to cause a fatal termination, although it may have been a contributory factor, seeing that vessels in the medulla contained droplets of fat.

Absorption of Histamines in Surgical Shock.

A more important cause of secondary wound shock is the absorption of histamine or toxic substances from the damaged muscles. The arguments advanced in favour of the absorption of toxins derived from damaged muscles are: (1) A number of these men suffering from pure muscle injury have died of shock. It has been established that microbic infection is not an important factor in these cases. (2) Great improvement may follow rapid amputation of a lacerated limb. (3) Bayliss has shown experimentally that violent damage of the muscles of an animal while under anæsthesia causes shock; but Crile would argue that when you damage a tissue, although that animal may not show any signs of feeling, it is nevertheless receiving nociceptor stimuli, and it is quite conceivable that these nociceptor stimuli reaching the great central station for pain, the optic thalamus, are unconsciously reflected down to the cardiac and respiratory medullary centres. Morphia, carefully administered—and it may be remarked that it is contra-indicated if there is cyanosis—will relieve pain and excitation of the nerve centres and help to prevent shock in severe wounds.

Experiments of Dale on Histamine Shock.

There is experimental evidence that absorption of toxins derived from damaged tissues play an important part in the production of shock; for Dale has shown that injection of histamines produces shock. In one case, after slow infusion occupying an hour, death took place from failure of the vital centres. During that time the cells had used up a certain amount of the basophil staining substance shown by the comparison of the appearance of the cells of the medulla and the large flask-shaped cells of the cerebellum with similar cells in the brain of an animal which died three minutes after infusion at once of the same amount of histamine. In this case of sudden death there was no time for the cells to use their stored energy substance; consequently they present a normal staining appearance.

The former experiment would represent what actually takes place in wound shock—viz., a slow poisoning of the vital centres. It may be presumed that in the former there was a slow and progressive fall of the blood pressure; in the latter there was a gradual fall. Four other brains are being investigated.

Vascular Theory of Shock: Exæmia of Cannon.

I have not said anything yet about the vascular theory; it was formerly held that in "shock" the blood pressure fell, owing to its accumulation in the capillaries and veins of the abdominal organs. But it has been found that this is not the case. There is, however, a concentration of the blood and stasis in the capillaries of the body generally, a condition which Cannon calls "exæmia." The plasma exudes through the capillary walls into the tissues; and in proof of this concentration is the fact that the hæmoglobin index is increased, likewise the blood cells count.

TREATMENT OF SHOCK.

Intravenous injection of salines proved useless; in some cases transfusion of citrated blood and gum saline solution, which was introduced on the assumption that it could not escape from the vessels, have raised the blood pressure and led to recovery; in others, as in the four cases of which I have investigated the brains, these measures were unavailing. Crile recommends introduction of fluids by natural methods—e.g., Murphy's drip enema of 5 per cent. glucose and 5 per cent. soda bicarbonate solution. Stimulants seem to be useless, also injection of adrenalin and strychnine.

I have already pointed out that all causes of exhaustion of vital energy, whether psychical or physical, predispose to primary and secondary shock. In the case of the wounded in battle, thirst, exposure to cold and wet, delayed evacuation, rough and prolonged transport to hospital, and suffering with acute physical and mental agony conspire together to sap the vital energy, and when in consequence of circulatory failure and toxæmia the vital centres of the medulla become refractory and fail to discharge impulses the blood pressure falls progressively, and eventually in spite of all remedial measures the circulation and respiration cease.

In secondary wound and burn shock I did not find hæmorrhages; I conclude, therefore, that in cases of true "shell shock" this condition is due to physical effects produced by the forces generated by the explosion, but in some cases to the poisonous effects of gases absorbed while the man is lying unconscious.

In resuscitation from surgical shock practical experience shows that the treatment of the following phenomena have yielded satisfactory results—viz., (*a*) the fall of blood pressure; (*b*) the fall of the body temperature; (*c*) the lessening of the volume of the blood. Experience shows that cases of hæmorrhage combined with little shock yield the best results.

In conclusion, I desire to say that a full report of the neurological changes will be published shortly by myself and Dr. Uno, of Tokio, who is at present engaged in making an investigation of the microscopic changes in my laboratory under my direction.

Bibliography.—Reports of the Special Investigation Committee on Surgical Shock and Allied Conditions, Medical Research Council. National Health Insurance, Special Report Series, No. 25, No. 25. Surgical Shock, Crile and Lower, W. B. Saunders and Co.

Lieutenant-Colonels Walter Lidwell Harnett, I.M.S., and Francis Kenneth Kerr, R.A.M.C., and Dr. John Sinclair have been appointed Esquires of the Order of the Hospital of St. John of Jerusalem in England.

AN EXTENDED CURFEW IN DUBLIN.—For some months past, writes our Dublin correspondent, the curfew hours in Dublin have been from 10 P.M. to 5 A.M. Unfortunately, a number of attacks on parties of military or police occurred recently in the streets between dusk and curfew, and after giving warning that if such attacks did not cease curfew hours would be extended, last week the military authorities ordered that in future curfew would begin at 9 P.M. instead of 10 P.M. As heretofore medical practitioners, clergymen, and nurses will be granted permits to be abroad on urgent professional business. The earlier hour of curfew will put great difficulties in the way of the various medical societies whose meetings have always hitherto been held in the evening. No doubt an attempt will be made to substitute afternoon meetings.

FURTHER NOTES* ON THE INTRAVENOUS INJECTION OF ANTIMONY TARTRATE.

LEUCODERMA AND SKIN COMPLICATIONS; ADMINISTRATION OF LARGE DOSES.

BY J. B. CHRISTOPHERSON, C.B.E., M.D. CAMB., F.R.C.P. LOND., F.R.C.S. ENG.,

TROPICAL DISEASES CLINIC, MINISTRY OF PENSIONS; LATE DIRECTOR OF THE CIVIL HOSPITALS OF KHARTOUM AND OMDURMAN.

THE temperature chart which I am publishing with this communication is that of a Sudanese boy, aged 18, a student at the Gordon College, Khartoum, during the course of treatment by the intravenous injections of antimony (pot.) tartrate for kala-azar. He was admitted into the Khartoum Civil Hospital on March 9th, 1918, and was given 87½ gr. of antimony (pot.) tartrate in 86 days by intravenous injections, and discharged on August 18th, cured so far as we could say. His was a well-marked case of kala-azar, with considerable enlargement of liver and spleen, and an intermittent temperature. He had noticed his illness for some months. Leishman-Donovan bodies found in splenic punctures on at least three occasions; no unfavourable complications such as ulceration of mouth, diarrhœa, œdema of legs, &c. In August, 1920, two years after the course, he was quite well, and subsequently he was accepted for permanent Government service.

In publishing this case I do not wish to advocate the habitual administration of large doses of antimony tartrate even in diseases for which it is appropriate; antimony and its derivatives are powerful and potentially dangerous drugs, and in all cases the minimum dose necessary is the dose to be given. My object is to emphasise the fact that a very considerable amount of antimony tartrate may be injected if necessary into the veins without ill-effect, and to comment on certain incidents and complications which occur during the course of the administration of antimony tartrate for kala-azar, and for other diseases within my experience.

The temperatures in the ordinary native wards of the Khartoum Civil Hospital are taken by the native attendants, more or less under the supervision of the resident doctors, and are charted twice daily. The chart published with this article, representing four months, corresponds to the ordinary kala-azar chart made under these circumstances, recorded approximately at 7 A.M. and 7 P.M. It does not show the characteristic kala-azar deviations of temperature during the 24 hours of the day, as it would had it been registered every two hours. The rise in temperature till noon, followed by a drop, and a rise again at 4 P.M., forming a notch between 12 and 4 P.M., would then have been apparent. (A similar notch occurs at the same period during the night,[1] making a notch in the chart during each period of 12 hours.)

The chart indicates: (1) That kala-azar is *curable* by antimony tartrate administered intravenously; this fact is now too well known to need comment. (2) That a large quantity[2] of the drug is sometimes necessary (87½ gr. in 86 days in this case) to effect a cure, and may be given with impunity, provided it is administered with care. (3) That 3 gr. of antimony tartrate[3] may be injected every other day with beneficial results for 16 times in 33 days, totalling 60 gr. in 48 days, doses gradually increasing from 1 gr. to 3 gr. (see chart, May 26th to July 11th). (4) That this may be done soon after the preliminary but insufficient course

---

* Previous references to the writer's work on the subject appeared in THE LANCET, 1919, ii., 299, and 1920, ii., 528 and 1200.

[1] Colonel C. Donovan, I.M.S., pointed this out to me and gave me a chart to show it.

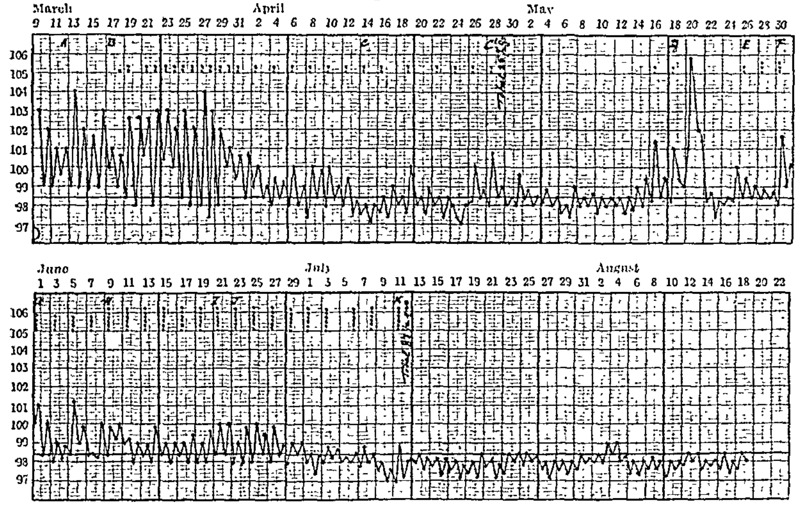
[2] A patient should be examined before commencing the course of injections in order to ascertain the existence or otherwise of contra-indications; stone, fistula, and certain renal complications often associated with bilharzia do not contra-indicate, whereas organic diseases of heart and kidney do contra-indicate injections for any reason. In far advanced cases of kala-azar it had best be withheld. My advice is, having ascertained that contra-indications are not present, inject with confidence.

[3] I have sometimes injected 4 gr. ant. pot. tart. at one time in cases of bilharzia.

(25·5 gr. in 41 days has been administered, during the early period of which 1 gr. antimony tartrate was given every day, afterwards every other day (see chart, March 17th to April 28th).

So much for the cumulative action of antimony. Of the more usual incidents attending the administration of antimony tartrate intravenously, the irritating cough at the time of injection—so constant when the potassium salt is used, but less frequent with sod. ant. tartrate—the metallic taste in the mouth and throat, the salivation, colic[4] and occasional diarrhœa, the nausea, retching, vomiting, the passage of a large quantity of urine two hours after injection, the occasional *faintness*[5] and collapse with cold clammy perspiration—of all these incidents only the cough, the metallic taste, and a little tightness or discomfort in the chest are frequent; in my experience they may indeed be considered almost as symptoms of the injection. When the others occur they indicate a need for caution. Cough, retching, *a little colic, and diarrhœa show that the maximum* dose for the time being has been reached. Jaundice and more albumin *in the urine than can be accounted* for by the disease under treatment indicate, in my opinion, *danger; when they occur permanent* organic damage to liver and kidneys will result if the injections *are continued. Both* liver and kidneys deal with the injected antimony tartrate, and their epithelium is liable to damage in the effort of these organs to eliminate it. To watch the effect of the antimony on the kidneys the urine should be examined after each injection. An attack of jaundice sometimes complicates the injections, indicating interference with the functions of the liver; but a much commoner complication indicating interference with the metabolism of the liver-cells by the antimony is shown by pains in the shoulders, and "lumbago" or muscular pains in arms or legs, sometimes so aggravated that the patient cannot turn over in bed. These pains appear to come on 4 or 6 hours after the injection, after a total of about 10 gr. have been given. At the same time the urine is loaded with crystals. In such a case it may be that certain products of digestion are not being elaborated as they normally should be by the liver, and the result is pain in various parts of the body of a rheumatic or arthritic nature, owing to the presence in the circulation *of "toxins" produced by the liver.* These pains usually pass off, but if they are severe it may be *advisable to suspend the injections or reduce the dose.*[6] They indicate interference by the antimony with the *normal metabolism of the liver.*

Kala-azar: Temperature and Treatment.



Each dot in temperature column represents 0·5 gr. ant. pot. tartrate. Total on April 29th, 25·5 gr.; on June 21st, 60·5 gr.; on July 11th, 87·5 gr. A, Blood negative for malaria. B, Leishman-Donovan bodies found; splenic puncture. C, Spleen measures 6½ inches below costal arch. C′, Total 25·5 gr. injected. D, Injections recommenced and suspended for a few days owing to reaction. E, Injections recommenced; *spleen 3½ inches below costal arch; 10 gr. quinine daily commenced. F, Splenic puncture negative; leucoderma* patches appear. G, 2 gr. P.A.T. per dose. H, 3 gr. P.A.T. per dose. I, Total 62 gr. J, Weight 8 st. 7 lb. K, Injections suspended; spleen normal to percussion; weight 8 st. 8½ lb.; total P.A.T. injected 87·5 gr.

Leucoderma.

This Arab boy had one very notable and, I believe, rare complication during the course of injections—namely, disturbance in the pigment distribution of skin and mucous membrane; he became piebald. Leucoderma began to appear after a total of 30 gr. were administered. (See Fig. 1.) Though occasionally one sees rashes, erythemata generally, I had not before seen this profound pigmentary disturbance of the skin during injections of antimony tartrate. The leucoderma areas are well shown in the photograph.

---

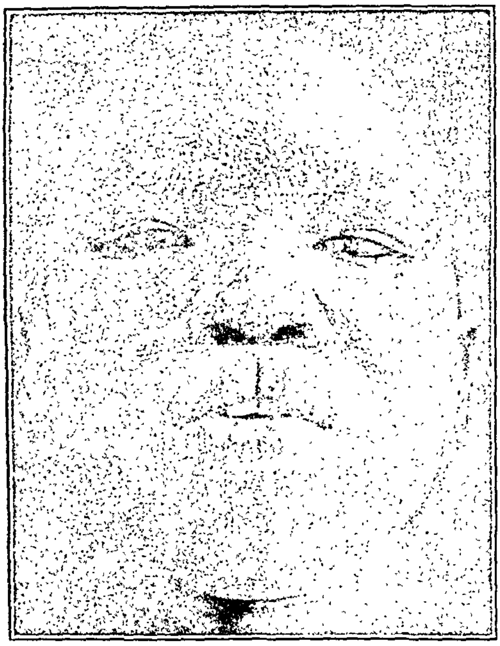
[4] An Englishman of 40, who had contracted bilharzia five years previously, complained of a pain in the abdomen half an hour after each injection when a dose of 2 gr. was reached; this was always *followed by a diarrhœa motion,* after which he felt quite well. Tolerance: In the course of antimony tartrate injections it sometimes happens, as in this case, that the patient retches, or, it may be, vomits *immediately after the injection even of 0·5 gr. If care be* taken not to increase the dose too rapidly and perseverance be exercised a tolerance is established. The patient under consideration retched on the table after first dose (½ gr.). Next day when given 1 gr. he vomited once. A day was omitted; on the next day (4th) he vomited again (once) after 1 gr. The drug was continued daily (1 gr.), and the patient established a tolerance at the eighth injection after 7½ gr. had been injected.

[5] *In certain cases due to idiosyncrasy or perhaps to faulty* arrangements, such as an indigestible meal previous to the injection, a patient will become dusky and drawn in the face, with contracted pupils and a slow *feeble pulse; for such a patient the* succeeding dose should be reduced and the arrangements adjusted.

[6] The pains are experienced when the full dose (2½ gr.) is being given; it is sometimes sufficient to reduce the dose by ½ gr. Another explanation of the "rheumatic" pains is that they occur when the drug reaches a certain concentration in the blood; this is *not so, however, because if* the amount of antimony is diminished by a smaller individual dose they do not recur, even although the concentration is greater after the reduced dose.

They appeared all over the body, but chiefly on the face and head (even on the palms of the hands and soles of the feet). On the face and body there were small, irregular, sharply outlined patches of absolutely white skin on the chocolate ground.

FIG. 1.



A. F., aged 18. Note white (leucoderma) patches on face, which extended all over the body; and lichen condition of skin.

Lichen planus.—A goose-skin or "lichen planus" condition (see Fig. 2) occurred somewhat earlier than the leucoderma and was distributed all over the body. I have noticed a "lichen planus" type of rash in other cases during injections of antimony tartrate, the shiny, velvety, smooth-all-over black man's skin becoming rough, dull, bumpy, and granular. Both these cuticular disturbances disappeared spontaneously, the "goose-skin" first, a month or two after the injections ceased; but, much to the boy's disgust, the skin of his lips remained a rosy pink instead of a dull red. These skin phenomena indicate that the skin is concerned in the elimination of the antimony from the patient; acting on this hypothesis, I have in two cases tried intravenous injections of antimony tartrate for chronic skin disease, psoriasis, with, I think, some success.

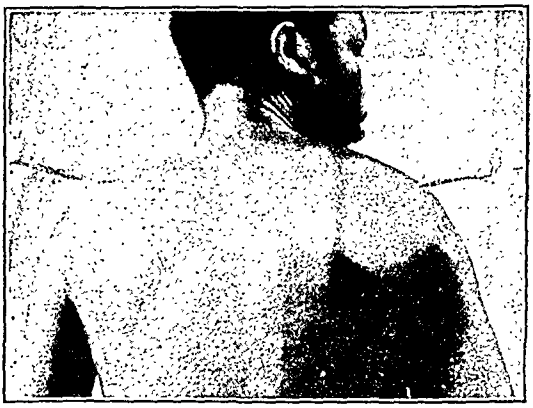
The doses of antimony tartrate recommended in bilharzia disease (20–30 gr.) have been described as "perilously high." They may be so; but they cure the patient and do him no harm.[7] The risks of antimony poisoning are known, and one naturally works with care. For the cure of internal leishmaniasis even larger quantities of antimony tartrate are required than for bilharziasis (it may be 87 gr., as in this case). Kala-azar is a formidable disease, and larger doses are justifiable. "Give as much antimony as the patient will stand in such cases, carefully checking the results of each dose; but give as little as is necessary," appears to be the sound rule for guidance. In India colloidal antimony has been recommended in order to reduce the amount of antimony tartrate necessary for kala-azar.

In the case of oriental sore (Delhi boil) as little as 5–8 gr. ant. tartrate intravenously injected is often sufficient to effect a permanent cure. To give as little as is necessary, and to stop dosage directly the object is attained, would seem to be the corollaries of the treatment. Trypanosomiasis appears to resist antimony to a greater degree than kala-azar. For none of these diseases does there appear to be a fixed (total) curative dose any more than there is a fixed single dose. Intravenous medication is empirical; the capacity of the vascular system of the individual can be calculated, but different organisms vary in their resisting power and different strains of the same organism vary in their power of resistance to A.T.

Doses also vary[8] *with the individual patient—one* person tolerates a larger dose of A.T. than another—but, speaking generally, it is a good rule to work on carefully until the objective is gained (or until danger threatens), in all diseases in which antimony appears to have a specific action.

The intravenous injection of antimony tartrate raises questions of considerable interest for the clinician. How is it that so large quantities of what we regard as a very potent and toxic drug may thus be introduced into the human body when the maximum dose by mouth is so small? The official (B.P.) dose of ant. pot. tartrate is $\frac{1}{24}-\frac{1}{8}$ gr., but one may with beneficial effect inject *into the veins at one dose 3 gr., and repeat it every* other day for 16 injections. (This is not a question of establishing a tolerance for the drug because under no circumstances will a patient tolerate such doses by mouth.) Another interesting fact is that a small dose only can be given by the mouth and practically none hypodermically, on account of its irritating and necrosing action; whereas as much as 3 gr. (in 10 c.cm. or less water) can be given without any local injury, and with no harmful effect on the general economy, provided it is injected into the lumen of the vein. Regarded as a tissue, the blood is capable of resisting a very considerable amount of rough treatment.

FIG. 2.



Showing lichen condition of skin of body during injection of pot. ant. tartrate. Also incidentally showing white leucoderma patches on face and body.

The intravenous injection of antimony tartrate also raises interesting biological questions. I have pointed out, when writing on the effect of antimony tartrate on bilharziasis, that the antimony circulating in the blood, killing the adult worms, also penetrates the shell envelope and kills the myracidium within. It would seem probable that it acts in the same way towards the Leishman-Donovan body whose envelope is also *permeable;* moisture disorganises this body—a dry syringe is necessary when splenic punctures are made for diagnosis of kala-azar—and we also know by experience how difficult it is to find the Leishman-Donovan bodies in the splenic or liver smears post mortem and in the sections of dead tissues, so sensitive are they to *the environment that directly death takes place they* disappear—i.e., break up, and cannot be demonstrated.[9]

---

[7] It has been stated that a total of 10 gr., or even less, is a sufficient quantity of ant. tartrate for the cure of bilharzia. A British army officer, who contracted bilharzia in Egypt two years previous to the course of injections, had 22½ gr. (total); eight months later slight vesical irritation recurred; a few live ova reappeared in the urine, and I gave him another course of 30 gr. On the other hand, an English boy of 8 years, from Nyassaland, was cured after a total of 9 gr. The killing dose appears to be a variable one; some strains bilharzia worms are more resisting than others.

[8] Young people take antimony tartrate very well. Older people with organs healthy except for the disease for which it is given—bilharzia: leishmaniasis—as a rule, take it well. In patients over 40 it should be given with more caution. Certain people appear to be unable to tolerate a full dose. It is always advisable to commence by a small dose of ½ gr., increasing it cautiously; when the maximum single dose has been found it may be injected every other day—in England it is usually considered to be 2½ gr. Some Soudanese I found tolerated 3 or even 4 gr. well, others showed signs of an over-dose when 1 gr. was reached. A patient in the latter stages of kala-azar will obviously not tolerate as large doses of a cardiac depressant, such as antimony tartrate, as will the ordinary bilharzia patient. The fact is that young people especially tolerate the injections well, and people with organic disease (especially cardiac), badly; there is a certain number of apparently healthy persons who are intolerant.

We can understand these facts if there be free and easy communication through the limiting membrane—the envelope of the L.D. body. The permeability of the L.D. body envelope or membrane is further indicated by the kala-azar temperature chart and also by the profound constitutional disturbances caused by the disease—the body inside the envelope manufacturing waste products, toxic to the human organism, which escape through the shell and are possibly replaced by pabulum passing in from without. Practical advantage is taken of the permeability of enclosing membranes of organisms when staining for the microscope, and I wish here to emphasise its clinical importance. Antimony tartrate kills the myracidium lying in the bilharzia ovum; after a few grains have been injected for bilharziasis the ova are very difficult to find in the urine, having apparently been arrested in their progress to the lumen of the bladder. This arrest is not easily explained if the ova are merely foreign bodies embedded in the tissues acting simply as such; if they were, they would behave in the same way *before and after injection. Normally they are* apparently vital bodies, having automatic action; it seems that only when the motor machinery inside the myracidium is killed by the antimony tartrate does it become a foreign body simply.

To return to the case of kala-azar under discussion. The enlarged spleen and liver *did not satisfactorily* diminish under A.T. injections alone; 10 gr. of quinine were therefore given every morning from 25/5/18 to 11/7/18 (47 days).[10] Quinine was apparently necessary to this end; 10 gr. of quinine daily were given by mouth for 47 days, after which the spleen could not be felt, and the liver was not enlarged to percussion and palpation. Administration of quinine, together with injections of A.T., is thus advisable in kala-azar, when the spleen and liver do not satisfactorily diminish in size.

In bilharzia, kala-azar, and I believe also in trypanosomiasis, the initial effect of injecting antimony tartrate is a marked increase in constitutional disturbance, shown in bilharzia by increase of blood in the urine and aggravation of the local symptoms, in kala-azar by the rise in temperature often to 106° or 107°, and in sleeping sickness by aggravation of symptoms. The first effect of intravenous injection of antimony tartrate is, therefore, to provoke the disease by liberation of toxins into the circulation. Later, as the blood stream becomes more laden with antimony, the parasites are killed. This point of view is supported[11] by the initial increase of eosinophilia in bilharziasis during the course of injec*tions; the differential* count of the white blood cells afterwards becomes normal. (The large mononuclear cells also increase when antimony tartrate is injected in bilharzia.)

Summary.

To sum up. Experience seems to show that a few grains of antimony tartrate (5–8 gr.) by intravenous injections may be sufficient to cure leishmaniasis of the skin,[12] *more (20–30 gr.) are necessary, as a rule, to bring* about a cure in bilharziasis, and still more (60 gr., perhaps, and more) are necessary for leishmaniasis or kala-azar, and possibly still more (probably in repeated courses) for the cure of trypanosomiasis.

Antimony tartrate (pot. or sod.) when given intravenously in appropriate dilution and administered with care may be given in larger total doses than is generally supposed.

The blood, considered as a tissue, is probably capable of withstanding more physical and chemical ill-usage than any other organ; *but owing to its structure and* distribution it is obviously incapable of resisting micro-organic invasion, and is the logical route for direct attack upon micro-organic and other diseases, particularly those of the blood stream itself.

The cure of parasitic diseases, such as bilharzia, kala-azar, *trypanosomiasis*, filariasis, dracunculus medinensis, by a drug given intravenously (the drug itself if it acts directly, or a derivative if it acts indirectly) depends on: (1) the permeability of the enclosing membrane (or skin) of the parasite; (2) the penetrating power of the drug which in turn depends on its physical condition or chemical structure; (3) the toxicity of the drug to the parasite.

---

[9] Although L.D. bodies may be found *plentifully in spleen and* liver smears, they are hard to find in the peripheral blood of a patient, in spite of the fact that the splenic blood-vessels communicate freely with the systemic vessels. Possibly they disintegrate when they find themselves in the peripheral circulation.

[10] The boy came from Cinga on the Blue Nile; possibly he had chronic malaria, although no malaria parasites were found in the blood.

[11] It is also supported by the temperature curve in *kala-azar* during the course of injections. Follow the chart published.

[12] Provided that the sores are not secondarily infected with a staphylococcal or streptococcal infection; otherwise they will not heal so soon, although the leishmanic infection will clear up.

THE OUT-PATIENT TREATMENT OF BILHARZIASIS,

WITH AN ANALYSIS OF 1000 CASES.

BY H. B. DAY, *M.C.*, M.D. LOND., F.R.C.P. LOND.,
PHYSICIAN, KASR-EL-AINI HOSPITAL, CAIRO.

THE war-time discoveries of the Bilharzia Mission under R. T. Leiper, and of J. B. Christopherson, N. H. Fairley, and others concerning the early signs of infection, the life-history of the parasite, and a specific remedy against it, have rendered possible a *campaign against the ravages of the disease in Egypt.* Since bilharziasis affects no less than 80 per cent. of the agricultural population in this country, it is evident that preventive measures must depend largely for their success on the awakening of an intelligent knowledge of the disease among the peasantry. It is hoped that by systematic instruction in the schools and by exhibition of posters and kinematograph films public interest will be aroused to the possibility of avoiding worm diseases and other infections and to the necessity of early treatment for curable maladies.

As a preliminary to work on a wider scale, it appeared desirable to test the methods of treatment advocated for bilharziasis, with a view of learning their possibilities and limitations. Experience soon showed that in-patient treatment was impracticable for most patients. The pressure on hospital beds prevented the admission of any but severe and complicated cases, and the average Egyptian would not stay in hospital unless seriously incapacitated. To overcome this difficulty permission was obtained from the Department of Public Health to erect a tent annexe at Kasr-el-Aini Hospital for the out-patient treatment of bilharziasis and ankylostomiasis. The particular subjects for investigation were twofold: (1) to test the practical value of out-patient treatment of bilharziasis as regards the attendance of patients and the efficacy of routine treatment; (2) to find the best methods of specific treatment and the minimum dosage and attendance necessary for the average case.

The annexe was opened in December, 1919, and put under the immediate charge of successive clinical assistants. To these doctors I am deeply indebted for all the clinical work and for invaluable assistance in the examination of the microscopic specimens necessary for scientific control. The annexe consists of marquee tents, pitched inside the hospital square, and arranged in two sections, male and female. They are provided with stretchers (on trestles) and blankets, and latrine accommodation is attached. A central marquee serves for examination and treatment. Each patient receives a numbered attendance card, which corresponds to a page in the registers in which all particulars are entered. At each visit a specimen of urine (or stool if indicated) is obtained and its appearance noted, while at appropriate intervals the specimen is kept for microscopical study.

Analysis of Cases Treated.

Number of patients.—The annexe has been well patronised from the start, being supplied from the numbers of bilharzial patients presenting themselves in the out-patient departments. From 100 to 200 new patients are seen every month, as is shown in the following table :—

1919.		Feb.	94	June	92*	Sept.	231
Dec.	44	March	111	July	174	Oct.	162
1920.		April	136	August.	124†	Nov.	169
Jan.	66	May	139				

* Ramadan Fast. † Bairam Holiday.

These numbers are exclusive of 115 ankylostoma patients also treated at the annexe during the last nine months.

For analysis the first 1000 cases have been taken :—

Sex.—There were 897 male and 103 female cases.

Age.—Patients were of all ages, ranging from 2½ years to over 60. 118 were children not exceeding 10 years of age.

Types of infection.—The great majority of patients were suffering from urinary disease, as is shown below :—

Bladder infection	875*	Bladder and intestine	29
Intestinal	26	Urethra only	1
Total			931

* Of these 111 were complicated by septic cystitis, 4 by fistula, and 2 by filariasis.

In addition, one case of chyluria (filarial) was also treated.

Selection of cases.—Only patients with active infection are suitable for specific treatment. The passage of blood at the end of micturition, or of bloody mucus with defæcation, is the usual clinical sign, and the diagnosis must be made by finding living bilharzia ova on microscopical examination. So long as living ova are present, the existence of secondary bacterial infections of moderate degree is no bar to successful treatment. But patients with advanced disease often present the signs of septic cystitis, and frequently pyonephrosis, while no ova, or only a few dead ova, are found on thorough examination. In such cases antimony treatment is useless, and therefore prejudicial to the reputation of the drug.

Contra-indications.—The chief of these, other than that above mentioned, is severe cardiac, arterial, or renal disease. Even a fairly advanced degree of hepatic cirrhosis need not be a deterrent, but doubtful cases are unsuited to out-patient treatment, and, indeed, cannot attend properly. We have also avoided giving antimony injections during pregnancy. On these grounds 68 out of the 1000 cases were rejected as unsuitable. Two bilharzial patients were admitted to the wards on account of their bad general condition, and two of the women were advised to wait until the termination of their pregnancy. Twenty-eight patients were rejected on account of advanced bladder and kidney disease, with no evidence of active bilharzial infection. The remaining 36 patients were found to be suffering from other diseases and not from bilharziasis.

Subsequent attendance.—One-third of the patients ceased attending after one to three visits, being unwilling or unable to continue treatment. Several returned later and took a full course. These return cases are omitted in the following table, which shows the total amount given in the ordinary way :—

Less than 5 gr.	313 patients.	20-25 gr.	55 patients.
5-10 ,,	215 ,,	25-30 ,,	84 ,,
10-15 ,,	146 ,,	Over 30 ,,	19 ,,
15-20 ,,	92 ,,		

Four patients refused injections; four others were treated by injections of colloidal antimony only.

On the whole these figures are satisfactory. Many of the patients had little disease, and to that they were well inured, so that the duration and inconvenience of the necessary treatment deterred them from continuing their course. A large number of patients ceased their visits as soon as their symptoms were relieved, as usually occurs within a week or two of commencing treatment. On the other hand, most patients with septic cystitis as a complication were diligent in attendance, though little benefit could be procured. The remainder, a considerable proportion, persevered and took as many injections as were deemed necessary.

Method of injection.—For good and rapid work a full light, a handy assistant, and a sharp needle on a glass syringe are needed. The requisite quantity of a 6 per cent. solution of tartar emetic (1 gr. in 1 c.cm.) is drawn up into the sterile syringe followed by some c.cm. of sterile saline. The patient lies on an operating couch with his arm extended and supported on a small three-legged table, with a Δ-shaped top, whose base abuts against the couch. The skin in front of the patient's elbow is swabbed with alcoholic picric solution by the attendant, who then grasps the arm above, while the patient clenches his fist to distend the veins. As soon as the needle has been shown to lie truly in the lumen of the vein by the free entry of blood, the attendant relaxes his hold and the injection is made. The patient then holds up his arm to arrest any bleeding and goes out to rest in the adjoining tent. The injections are given in the middle of the morning when the stomach is fairly empty and the drug has least untoward effect. Special care is necessary in making the injection, since tartar emetic is a most irritating compound to the tissues and causes severe inflammation if introduced outside the vein.

Course of treatment.—To adults was given an initial dose of 1 gr., 1½ gr. the next time, and 2 gr. on each subsequent occasion. Not many out-patients could take a larger dose without suffering from persistent giddiness and often vomiting. Young women and youths generally took 1½ gr. as a full dose, and it was found that many children could tolerate this amount. The injections were given as a rule on alternate days. Many patients were somewhat irregular in attendance and received only two, or even one, injection per week. The duration of treatment was controlled by observing the effect on the ova.

Examination of ova.—The urine is allowed to stand in a specimen glass; its appearance and the nature of any deposit is noted. The lowest layer is then transferred to a centrifuge tube and washed by centrifuging and shaking with successive quantities of water. Since the ova are relatively heavy they are brought down by a few turns of the handle, while most of the blood and pus corpuscles are left suspended, and can be poured off with the supernatant fluid. The sediment is finally transferred by a pipette to a shallow glass cell affixed to a microscope slide. By filling the cell above its brim and dropping on a cover-glass air bubbles are avoided and evaporation retarded, if it is desired to postpone examination until living miracidia have hatched out. Half an hour in an incubator at 37°C. will hasten matters in cold weather.

Under regular treatment by tartar emetic the phenomena outlined by Christopherson[1] occur as follows :—

(*a*) By the end of the first week there is a noticeable diminution in the amount of blood and number of ova passed in the urine. In mild cases blood is no longer visible to the naked eye.

(*b*) About the ninth day the ova begin to hatch out more slowly; the miracidia are less active and die quickly.

(*c*) By the end of the second week a considerable proportion of the ova fail to hatch. The shells of these ova are distended as usual by imbibition of water, but the enclosed miracidia show little or no movement. Small immature ova are frequently seen whose contents appear brown and granular instead of a translucent clearness.

(*d*) During the third week the toxic effect of the drug becomes very evident. The few miracidia that hatch out are usually globular in shape, move very sluggishly, and soon die in distorted shapes. Most of the ova no longer swell in water, while the delicate and refractile structure of the contained miracidium becomes obscure and granular. Death of the embryo is followed by a deepening opacity; the contents of the shell become brownish, and ultimately black, by transmitted light. This change occurs first in the cells and granules around the embryo, and later in the degenerated miracidium itself.

(*e*) By the end of the third week or during the fourth all the ova are dead, most being black. These black ova are often passed in masses held together by mucus. As many as 200 to 300 may sometimes be found in a specimen of urine even a month or longer after the conclusion of treatment, but in most cases the ova become scanty and difficult to find.

Similar phenomena are found in the case of intestinal disease due to the *Bilharzia mansoni*, with its lateral-spine ova and slightly larger miracidia. It should be borne in mind that ova left in contact with fæces or alkaline urine perish quickly, and so often fail to hatch on the subsequent addition of water. Also, that rough handling will rupture the shells of ova whether dead or alive, so that the finding of an empty shell is no proof of a living embryo. A preliminary search of the specimen before the ova have time to hatch naturally will obviate this error.

Immediate results.—The effects of injections on the ova are shown on the charts in diagram form. The curve shows the percentage of dead ova present, not the total numbers, and the figures beneath record the dose in grains of each injection. Chart 1 illustrates a typical case. When injections are given at long intervals the effect is delayed, as is well seen in Chart 2. To secure a quick result it is important to raise the concentration of antimony in the circulation by giving frequent injections in the first week. Chart 3 records the results in three patients of identical weight, who received different amounts of the drug during this period. *In each case eight days* elapsed before any definite effect was observed, but the subsequent progress varied in rate of cure. Occasionally one can observe the effect of one or two doses only, which is characteristically transient (see *Chart 4*). Now chemical analysis of the urine of patients has shown that the excretion of antimony is maintained for some two or three weeks at a high level after the termination of a *full course of tartar* emetic.[1] This fact, coupled with the special influence of an early concentration of the drug on the ova, made it appear possible to obtain the curative effect of the remedy by quite a short course of treatment, thus taking advantage of the cumulative action of antimony. On trial this method was found to succeed, four or five injections (a total of 8 to 9 gr.) being sufficient to kill the ova if given in the first ten days or so, and their effect looked for at the expiry of the usual interval—about a fortnight later (see Chart 5).

Late results.—Further experience proved that this short course was unsatisfactory, since re-examination two or three months later showed the recurrence of living ova in patients who had not been exposed to reinfection. Few adult *patients appear to have been* permanently cured by a smaller dose than 18 gr., although the number of ova may be very greatly reduced when seen some months afterwards. The occasional *finding* of a living ovum after a full course of treatment may be explained by the survival of ova which *have possibly* been protected against the influence of the drug by lying enclosed within a giant cell, as is not infrequent. But the reappearance *of living ova* in increasing numbers can only mean the presence of living worms. Hence we may conclude that the primary effect of antimony in bilharziasis is the destruction of the *ciliated embryos* within their shells, and that the parent worms require a larger lethal dose. This result is more in keeping

In the following Charts the Curve shows the Percentage of Dead Ova present on Examination of the Urine (reading from the left). The figures beneath record the Dose in Grains of each Injection.

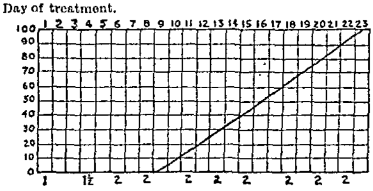


CHART 1.—Male, age 22, weight 10 st. Bilharzia of bladder 15 years, of intestine 1 year. Treated with tartar emetic (intravenous injections).

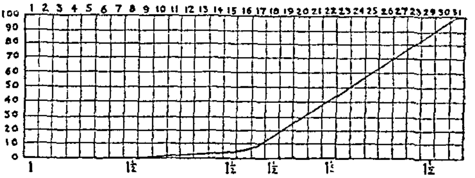

CHART 2.—Girl, age 11, weight 5 st. 1 lb. Bilharzia of bladder 1 year. Treated with tartar emetic (intravenous injections).

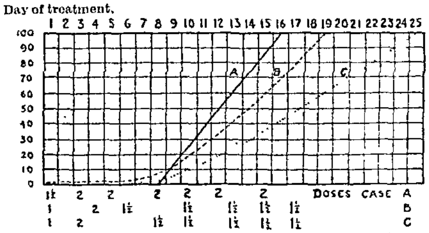

CHART 3.—To show the comparative progress in three patients with bilharzial disease of bladder. Ages 19 to 26, weight of each 9 st. 9 lb. Treated with tartar emetic (intravenous injections). In spite of the small total dose permanent cures were obtained.

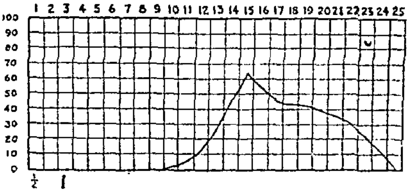

CHART 4.—Boy, age 7, weight, 2 st. 12 lb. Bilharzia of bladder 15 months. Treated with tartar emetic (two intravenous injections).

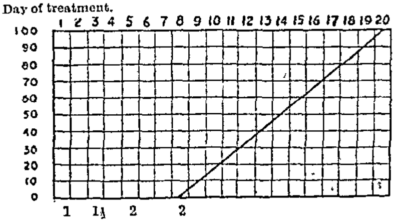

CHART 5.—Male, age 21, weight 9 st. 12 lb. Bilharzia of bladder 10 years. Treated with tartar emetic (intravenous injections).

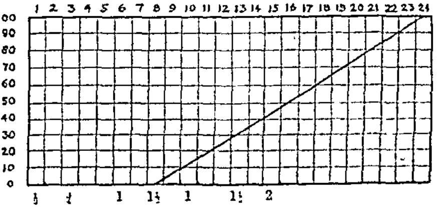

CHART 6.—Girl, age 8, weight 3 st. 13 lb. Bilharzia of bladder 5 months. Treated with emetine (intramuscular injections).

with the experience of Sir Leonard Rogers[2] (which we have confirmed), that in the *treatment of filariasis* a large amount of antimony is necessary to reduce permanently the numbers of microfilariæ in the circulation. The bilharzia worm can be found alive in the portal vein for many hours after the death of the patient from toxic diseases, and on experiment is found to resist quite considerable concentrations of antiseptics. Leiper and Christopherson inform me that they believe the bilharzial ovum is endowed with the power of digesting its way through the tissues. Hence the *reduction of the hæmaturia and number of ova passed* in the first week of treatment may be explained by a functional disability of the miracidia preceding their death, and not necessarily by a similar effect on the egg-laying worms.

Optimum dose.—For adults we may place the minimum effective dose at about 13 gr., but a larger amount is generally necessary. For considerable variations are observed in the amount of antimony needed to cause permanent disappearance of living ova. Thus two brothers, aged respectively 13 and 17, attended the annexe together and received the same number of injections. The elder received a total of 28½ gr., and six weeks later his urine was found to contain a very few dead ova. The younger received 19½ gr., but had a more severe infection, and six weeks after the course was terminated a specimen of urine contained seven living and two dead ova. A specimen before treatment contained some hundreds of living ova, so that treatment could not be considered a failure. Even a total of 25 to 30 gr. has not uniformly succeeded in permanently banishing living ova. It is probable that the effect of treatment depends to some extent on the condition of the worms and the ova present. An adult with disease contracted in childhood who has not been exposed to reinfection for years may need a smaller dose for his cure than would another patient recently infected with vigorous parasites. This theory may explain why 12 gr. can cure one case, while double that amount may be needed for another patient of similar size.

As the result of our experience with out-patients the following course is recommended for an adult:—

1st week:	Daily injections ...	1	1½	1¾	2	2	2	2 gr.
2nd "	Injections ...		2		2		2	"
3rd "	alternate days ...		2		2		2	"

The amount of each dose is regulated by the size, condition, and tolerance of the patient. Under this system the usual course for an adult totals 24 gr., and the omission of one or two doses owing to irregular attendance will hardly affect the result.

The urine is examined at the end of the course and again after a week, when a further course can be given in the unlikely event of ova surviving. The patient should report about three months later.

Complications.—Specific treatment is of great value before operations are undertaken for the closure of urinary fistulæ or excision of polypi, &c., complicating bilharziasis. Thus F. O. Lasbrey and R. B. Coleman[5] at the C.M.S. Hospital, and the members of our own surgical staff, find that post-operative healing is vastly accelerated in such cases once the causative infection has been removed. About 10 per cent. of our cases of urinary bilharziasis are complicated by a secondary septic cystitis. If the amount of pus present is quite moderate the cystitis generally disappears after the ova are killed, but a severe cystitis is hardly affected, though hæmorrhage usually ceases.

Treatment by other drugs.—The effect of other remedies has been tested and new preparations are on trial. Colloidal antimony is effective, but the ampoules only contain about 2 c.cm., a dose which is only successful in quite small children, adults requiring 5 to 10 c.cm. each injection. This preparation has the great advantage that it can be given by intramuscular injection. Emetine in large doses has been found effective by Diamantis[3] and A. Erian,[4] and we have confirmed their results. The remedy is best given intravenously, as a large dose is irritating to the tissues. The dose is from ½ to 3½ gr. for each injection, according [illegible]e weight and tolerance of the patient, and the course is similar to that for tartar emetic. Chart 6 illustrates *the effect on the ova produced by a course of emetine.* The high cost of emetine militates against its routine use for out-patients. But it is a most useful alternative to use under certain conditions, viz.: (*a*) for young children or others whose veins are too small or inconspicuous for intravenous injections; (*b*) for patients who exhibit an intolerance for tartar emetic or where an error in technique has resulted in abscess; (*c*) for cases of bilharzial dysentery complicated by amœbiasis.

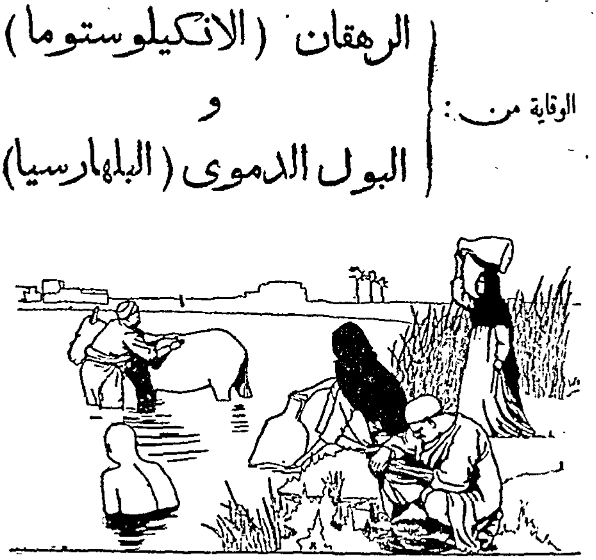
Ankylostoma Patients.

Cases without severe anæmia have been treated as out-patients in the annexe. The patient is instructed to come fasting in the morning but to bring some food with him to be taken after treatment. He is accommodated on a stretcher and is given 10 drops of oleum chenopodii on sugar at intervals of one and a half hours until three doses have been taken. One hour later he has a dose of castor oil. Before he leaves he has his food and is given a bottle of iron and arsenic mixture to take home. The treatment is repeated in three days and the stools re-examined after a fortnight.

For the detection of the ankylostoma ova in the fæces the flotation method has proved most convenient and satisfactory. A small portion of fæces is emulsified in a little water and poured through a coarse strainer into a small flask of conical shape, narrowing to the neck. (A small bottle with sloping shoulders and a wide mouth does equally well.) The flask is then filled to the brim with a saturated solution of common salt in water and left to stand for a few minutes. Portions of the surface film are then taken up by means of a wire loop dipped under the surface and transferred to a slide for microscopical examination. The ova are found concentrated in this surface film, and can be identified with the greatest ease.

Work in the Provinces.

The success of the special annexe at Kasr-el-Aini led the Department of Public Health to open similar establishments in connexion with three provincial hospitals in the Delta last summer. These annexes have proved very popular, and their usefulness has been enhanced by the local exhibition of posters, by public lectures, and by the distribution of leaflets. I am indebted to Colonel Garner, Under Secretary of State, Department of Public Health, for permission to reproduce the illustrated heading of one poster, which draws attention to the danger of infecting water.



An Egyptian poster heading designed to inculcate the danger of water-borne disease. The Arabic words above the picture signify, reading from right to left:—

The prevention of { Anæmia (Ankylostoma)
and
Hæmaturia (Bilharzia).

Conclusions.

1. The out-patient treatment of bilharziasis on a large scale is practicable and successful. 2. Due selection of cases and great care in giving the injections is necessary. 3. The primary effect of antimony is on the ova. 4. A full course of tartar emetic or alternative drug is required to secure a permanent cure in most patients. 5. Colloidal antimony and emetine are useful substitutes for tartar emetic when occasion demands. 6. Curative treatment must be combined with the widest measure of public instruction if the incidence of the disease is to be lessened.

MOSQUITO-NETS: THEIR USE IN THE PAST.

BY SIR PATRICK HEHIR, K.C.I.E., C.B., C.M.G., M.D., MAJOR-GENERAL, I.M.S. (RETIRED).

SOME months ago a very useful book on tropical medicine was reviewed in THE LANCET.[1] In tracing the history of malaria in that work it is stated, inter alia, that mosquito-nets were first used in India in 1881. I would ask the author's permission to allow me to correct this statement. The mosquito-net is much more venerable in India. We have it on record by Surgeon-Major (afterwards Sir James) Annesley, I.M.S., in his "Diseases of India," that mosquito-nets were used as a protection against mosquitoes by Europeans as early as 1828, when his book was published, and possibly they were used at an earlier date. They were then employed, Annesley tells us, to prevent the physical discomfort caused by the bites of mosquitoes, to exclude the "miasmata" that were supposed to give rise to malaria, and to "prevent chills from the night dew." Where the author of the first book referred to above got his date from I do not know; the practical application of Sir Ronald Ross's discovery of the direct relation of mosquitoes to malaria did not form part of routine life in India until the beginning of the present century.

Long before the discovery of malaria parasites by Laveran in 1881 nets were in use in several tropical and subtropical countries. We have it on record as a historical fact that almost a century ago some of our generals and sportsmen in India attributed their freedom from disease to the using of mosquito-nets. I can personally remember mosquito-nets being in use at Poona, Mhow, and Nasirabad when my father's regiment, "The King's," went out to India in 1868; their use was not general at that time, and they were not issued to British troops as they are now.

The native of India has always used his *chadar* (sheet) or other covering when asleep to protect himself from the attacks of mosquitoes. Even in the hottest weather we find him covering his head and exposed parts of his body with such a garment. I dimly recollect being told or reading somewhere that the Singhalese several centuries ago used some form of a net or covering to protect themselves from mosquitoes. I regret I cannot recall the reference.

Probable Early Antimalarial Measures.

It is possible that if we could ferret out the whole history of the mosquito-net we might find that through the ages the inhabitants of countries infested by mosquitoes have used some sort of protection against their attacks, either in the form of nets or covering, or as applications to the surface. The habit of anointing with scented oils practised by the Babylonians and other ancient Semitic nations may not have been without its purpose in repelling the attentions of insect life. The Tigris and Euphrates valleys must have been a paradise for insect life from time immemorial. One can never forget the appalling pestilence of insects that invaded the 6th (Poona) Division during the first week of June, 1915, at Ezra's Tomb on the Tigris, a place between Basra and Amara. We have the authority of history indicating that some form of mosquito-net was in use thousands of years ago by Egyptians, Greeks, and Romans.

Herodotus and Mosquito-Nets.

A few months ago I was reading Cary's English version of Herodotus and came across an interesting paragraph in this connexion (II., p. 94). Writing of the Egyptians who dwelt on the banks of rivers, lakes, and marshes, Herodotus says:—

> "*They have the following contrivance to protect themselves from* musquitoes (*sic*), which abound very much. The towers are of great service to those who inhabit the upper parts of the marshes; for the musquitoes are prevented by the winds from flying high; but those who live round the marshes have contrived another expedient instead of the towers. Every man has a net with which in the day he takes fish, and at night uses in the following manner: in whatever bed he sleeps, he throws the net around it, and then getting in, sleeps under it; if he should wrap himself up in his clothes or in linen the musquitoes would bite through them, but they never attempt to bite through the net."

One imagines that the Egyptian fisherman had either great faith in the protection afforded by his net, or he had more confidence in the guilelessness of the genera of mosquitoes inhabiting his neighbourhood than we now entertain as regards mosquitoes of tropical and subtropical countries.

The Roman Conopeum.

History likewise tells us that the *conopeum*, or mosquito-net, was used by the Romans. In an admirable résumé of this subject Sir Ronald Ross[2] quotes Varro, Horace, Propertius, Juvenal, and Paulus Silentiarius as referring to the mosquito-net, and tells us that Horace says: "And among the military standards, oh shame! the sun sees a mosquito curtain," and that Propertius calls these nets *foeda* (foul or disgraceful); it may be supposed he meant that it was unmanly for the hardy Roman soldier to indulge in the use of such protection against gnats. Personally, I feel that the man who devises a practicable and portable means of protecting troops who are fighting in endemic malarial areas from the attacks of mosquitoes will deserve the highest commendation.

The Possibility of Complete Protection.

The well-known experiment of Drs. G. C. Low, L. W. Sambon, and D. Rees, carried out in the Roman Campagna in 1900, proved beyond all equivocation that if the body is protected from the attacks of anopheles one may live in even the worst endemic malarial areas without becoming infected. If I remember rightly, Professor J. W. W. Stephens and Lieutenant-Colonel S. R. Christophers, I.M.S., found the same to be the case in their malaria work in the West Coast a short time afterwards.

In quite recent times one has often been asked seriously by civil servants, military officers, and other educated people in India whether mosquitoes really carried malaria. If some of the better classes entertain doubts of this kind, it is scarcely to be expected that the poorer, uneducated classes in India, including the village ryot, knows what a danger to his health the mosquito is. Yet we require the coöperation of all classes in the reduction of malaria. This points to the necessity of educating the people of India, especially the agricultural population, in the first principles of prevention, and to the fact that for many years to come we should patiently and persistently diffuse this knowledge by propaganda, placards, leaflets, lectures, magic-lantern, microscopical, and kinema demonstrations and other means. I gave lectures of this kind for years to various garrisons and other audiences in India.[3] They were usually associated with magic-lantern slide demonstrations of the different forms of adult anopheline and culicine mosquitoes, their larvæ and eggs, malarial parasites in the stomach walls of anophelines, in the blood, and of patients suffering from malarial enlargement of the spleen and malarial cachexia, and taking the classes or audiences to pools containing larvæ and eggs, and showing where adult mosquitoes hid in houses and huts during the daytime.

Prospects of Reduction of Malaria in India.

Even in the most advantageous educational circumstances it will be many years before the poorer classes in India give their whole-hearted coöperation to antimalarial measures. The task of the antimalarial worker in India is so immense that it may sometimes seem too formidable to tackle, but I am convinced that eventually, it may be a generation or so hence, persevering effort will bring about a reduction of malaria. We know how it has been greatly reduced in a large number of cantonments, both in India and Burma; this has only been achieved by the continuous and persistent effort of a host of enthusiastic medical and military officers and engineers who had faith in the results of their work; were there to be any relaxation of antimalarial measures in garrisons our troops would soon be as seriously affected with malaria as they used to be antecedent to the discovery of the relation of anopheles to the disease.

In drawing attention to the history of mosquito-nets I should like to say that personally I do not consider their use the real solution of protection from adult mosquitoes. Lakhs of rupees are spent annually on them, and even when employed with care their life is seldom longer than three years. The universal introduction in endemic malarial areas of wire-gauze mosquito-proof material into all permanent buildings is much more efficient, and eventually much more economical, than ordinary mosquito-nets. There should be no difficulty in insisting that all new buildings are provided with such wire protection.

TREE-BREEDING ANOPHELINES.

BY B. BLACKLOCK, M.D. EDIN.

(*From the Liverpool School of Tropical Medicine.*)

DURING the war a case of indigenous malaria was reported from Belton Camp, Grantham. Professor J. W. W. Stephens, Lt.-Col., R.A.M.C., examined the camp on Sept. 29th, 1917, and found there at one spot, somewhat remote from the lines where the case was, larvæ of *A. bifurcatus*. A. Macdonald[1] found *A. maculipennis* adults in small numbers in stables and pigsties near Belton Park in July, 1918, and quotes a statement that *A. maculipennis* larvæ had been discovered at Belton in August, 1917, by Stephens. In January, 1921, I went to the site of this camp and found, in a pond across a road from the lines where the case occurred, numerous larvæ of *A. bifurcatus*, and also a few in a ditch near the boundary fence of the camp. The pond and ditch when examined by Stephens yielded no anopheline larvæ. Turning attention next to the trees I discovered within a short period cavities containing water in an oak tree in the centre, and in a Spanish chestnut tree at the top, of the lines in which the malaria case occurred. In the pooled fluid siphoned off *A. plumbeus* larvæ were found in numbers, and also larvæ of *O. geniculatus*. My visit was undertaken at Stephens's request, as he was not satisfied that his discovery of *A. bifurcatus* larvæ in 1917 was adequate proof that this was the probable carrier. At the time of my visit the camp buildings had been removed, and with them apparently the pigsties and stables referred to by Macdonald, as I saw no sign of them. The Belton Camp country contains very fine old trees in large numbers, and would at a glance be chosen as a place in which *A. plumbeus* should easily be found. There is no evidence that *A. maculipennis* was the carrier in this instance, and any statement which assigns to it the rôle of transmission here must obviously be based on the assumption that *A. maculipennis* is the only anopheline which is worthy of consideration in this country. That such an assumption is hardly justifiable will,' I think, be admitted when the subject is considered more fully.

The object of the present paper is to draw attention afresh to the necessity of taking tree-breeders into consideration, and to urge the view that even with our present limited knowledge of their powers of transmission they constitute a factor which must not be ignored, whether in making anopheline surveys or in dealing with anophelines from the sanitarian's standpoint.

Habitual and Occasional Tree-breeders.

The true tree-breeding anophelines comprise those which breed normally in trees. They are represented in America by *A. barberi*, Coq., in Europe by *A. plumbeus* Steph., and in India by *A. plumbeus*, *A. annandalei*, Prashad., and *A. culiciformis*, Cog. All these species breed in rot holes and cavities in trees, and although there have been occasional records apart from trees (there is a single record by F. V. Theobald of *A. plumbeus* in a peat bog, and H. Cogill,[2] 1903, states that *A. culiciformis* has been found breeding in forest puddles or pools) they show little or no adaptation in this respect. The South American bromeliaceous species—e.g., *A. lutzi*, &c.—are, like the tree hole breeders, limited to such habitats. The occasional tree-breeding anophelines include *A. costalis* and *A. eiseni*, which normally breed in ground waters, and it is not yet established to what extent they may acquire the habit of breeding in true rot holes, which are little exposed or at high levels in trees.

The amount of importance attached by observers to those anophelines which breed in trees has varied in such a degree at different periods and in different countries that it appears opportune to reconsider the subject. R. Ross[3] recognised early the importance of the tree factor, and that in prophylactic measures tree breeding-places should be considered. In a footnote to certain clauses which he drafted with a view to embodiment in the local ordinances of Mauritius he states:—

> "Some specific provision ought to be made to enable the sanitary authority to fill up with concrete, or otherwise to treat, holes and hollows in trees which breed, or are likely to breed, mosquitoes. Similar recommendations have been made in various countries and districts by the authorities."

C. F. Lasalle,[4] in his conclusions to his Report on Trinidad and Tobago, emphasises that what is to be aimed at in the elimination of malaria is to free all towns, villages, and inhabited portions of estates, as well as a surrounding area within a radius of not more than a quarter of a mile of all permanent or potential mosquito breeding-places. It is noteworthy that in his detailed instructions to inspectors the following occurs:—

> "Every collection of water, and every receptacle liable to contain water (holes in trees, water-retaining plants), should be carefully examined."

Macdonald, on the other hand, dealing with indigenous malaria in England and the mosquitoes which are responsible for it, in his paper of 80 pages devotes only half a page to *A. plumbeus*, which is a tree-breeding anopheline occurring in the British Isles.

Some Reasons for the Neglect of Tree-breeders.

If we take *A. plumbeus* as a type of the tree-breeding mosquito, we can quote the following, among other reasons, why they are not regarded seriously. The question arises whether these reasons justify the relative neglect of this species and others of similar habits.

(1) They do not appear to be numerous. There is a considerable array of evidence to show that the anopheline which is most numerous in any locality may be relatively harmless as regards transmission of malaria, while one which is much less numerous may cause real damage. Ross[2] mentions as an instance—

> "as we showed in the case of *Myzorhynchus mauritianus*, a species may abound in a malarious locality, although the disease is really being spread by quite another one."

(2) They do not appear to be domesticated mosquitoes in the sense that they commonly enter houses for the purpose

[3] Ross, R., 1910: The Prevention of Malaria, pp. 191 and 636.

[4] Lasalle, C. F., 1920: Report on Anopheline Survey of the Colony of Trinidad and Tobago.

of biting man and remain in houses after biting. The test of domesticity in this sense is liable to lead to error, because we have very little evidence to show that only those anophelines are important which choose to enter houses for food and remain there after feeding. The fact that a species—e.g., *A. rosii* in India—is commonly caught in houses and is obviously domesticated is not in itself sufficient to warrant an assumption that a species which is not thus domesticated has little importance as a carrier of disease. Christophers[5] has shown that females of *A. plumbeus* gorged with blood retire to the tree holes, which, besides forming ideal breeding-places, are also safe and dark resting-places for engorged females. We know that *A. plumbeus* will feed on man at any hour with the greatest avidity, in laboratory conditions, when enclosed in feeding cylinders, and also when allowed to fly free in a mosquito-proof room. Further, Christophers ascertained that females in nature enter houses and bite freely in the mornings and evenings, but more especially in the mornings. We know also that the bite of *A. plumbeus* is, to many people at least, so little painful that it is often difficult to feel the bite, whereas both *A. maculipennis* and *A. bifurcatus* usually leave no doubt in the mind on this subject. For these reasons it is clear that without being domesticated in the sense mentioned above, this species of anopheline may play a part in nature in the transmission of malaria.

(3) They are not known to carry in nature. To refer again to the War Office work, it may be said equally of the other two species that they are not known naturally to have salivary gland infection in England. It may be said, further, that in laboratory experiments done in England with the three British anophelines, only one has so far been proved capable of developing malaria sporozoites in the salivary glands, and that one is the tree-breeder *A. plumbeus*.

(4) They are sometimes difficult to find. This seems to be the real cause of their being ignored and depends to a great extent, in so far as the adults are concerned, on the foregoing considerations. There is reason to believe, however, that so far from their being a rarity, when looked for in a systematic manner, they will prove to be quite common everywhere in the British Isles. The fundamental difference between *A. plumbeus* and *A. maculipennis* appears to be that whereas an idea of the prevalence of the latter may be obtained without difficulty both in the aquatic stage and in the imago stage, the prevalence of the former can usually be estimated best in the aquatic stages. The estimation of their prevalence even from the aquatic stages is not an easy matter, as the following considerations show. Blacklock and Carter,[6] during investigations on the breeding-places of *A. plumbeus*, showed that in the examination of 2500 trees taken at random and tested up to a height of only 25 ft. breeding-places of this species were found 15 times. They draw attention to the fact that it is not sufficient to look for large apertures in trees visible at some distance, but that each tree must be most carefully scrutinised in order that small and inconspicuous holes may be discovered. In one Spanish chestnut, recently, an aperture of only 1 in. in diameter, situated at 7 ft. from the ground, gave admission to a large cavity containing numerous *A. plumbeus* larvæ. Branches of moderate size have presented small apertures which led into large cavities in the trunk containing larvæ of *A. plumbeus*; water-holes have been found at a height of 32 ft. from the ground. In view of these observations it is not overstating the case to say that no survey for anophelines and no measures directed against them are complete which do not take into consideration the tree-breeding forms.

Conclusions.

1. In a survey for anopheline mosquitoes in any area where trees, even in small numbers, are present, any forms which pass their aquatic stages in trees must be considered equally with the forms which pass these stages in the ground waters.
2. Without the information with regard to the tree-breeding anophelines the survey is incomplete and adequate remedial measures cannot be applied.
3. An examination of trees for the purpose of detecting possible anopheline breeding-places involves very close inspection of all parts of the tree and its larger branches to a level as yet not determined, but higher than 32 ft. from the ground.
4. Generalisation with regard to the rise or fall of malaria in any area (whether marshy or not) which contains trees may be very misleading if such effects on anopheline breeding-places as may result from tree felling, tree planting, and decay of trees are omitted from consideration.

A CONTROLLED
STUDY OF SANATORIUM RESULTS.[1]

BY E. WARD, M.D. CAMB., F.R.C.S. ENG.,
TUBERCULOSIS OFFICER, SOUTH DEVON.

WHEN going over the results of sanatorium treatment which are so frequently published, the reader usually finds himself wondering what would have happened to these patients if they had not gone to a sanatorium. The present paper is an attempt to answer this question by comparing the after-results personally observed in 270 cases treated at sanatoriums with those in 597 cases treated by other methods. No research worker in physiology, or in any other field of science, would dare to draw conclusions without controls, yet the majority of our conclusions on the value of different forms of medical treatment are reached in this manner. There are, of course, notable exceptions, such as digitalis, antidiphtheritic serum, and vitamines.

In a prolonged discussion on the value of different treatments in pneumonia, which raged in the *British Medical Journal* some two years ago, most diverse remedies were praised, almost as specifics, by various writers, and the reader was led to ask himself what the mortality in A's and B's patients would have been if they had exchanged their specific remedies. Yet ample material to control our methods is at hand in the homœopathic hospitals and other institutions where some special line of treatment is followed. The surprising fact is that this has not already been done. Perhaps the General Practitioners' Association for Collective Research will one day take it in hand.

It must be admitted that Bardswell, in the report published by the Medical Research Council, points out the importance of a comparison of sanatorium results with the results of other forms of treatment.

Methods Employed.

In this inquiry the condition of 270 sanatorium cases two years after leaving the institution is compared with the condition of 597 controls two years after commencing treatment. This period is enough to allow the increase in weight and improved appearance manifest in most patients when they leave a sanatorium to have passed off, and gives a fair comparison. To gain further information, and to check the two-year results, a further series of 121 sanatorium cases, and 282 controls, is considered after a four years' period. The numbers are smaller because only cases seen personally have been considered, and sufficient time has not elapsed for me to follow up more cases for four years.

The controls were not sent to a sanatorium because they were unwilling or unable to go, because accommodation was not available, or because it was decided to keep them under observation for a while before sending them, and so avoid for them the sanatorium stigma.

The number of sanatorium cases lost sight of after two years is about 2 per cent., not sufficient to affect the result in any way, and I could, moreover, lay hands on reliable information about most of these, if time and energy allowed. Between the two and four years, another 1 per cent. may have been lost. Among the control cases rather more have been excluded for this reason, because visitors and other birds of passage are seen from time to time, but practically all the genuine Devonian cases can be traced.

A few words as to the method of classification are necessary.

When reporting on insured cases to the Devon Insurance Committee, in order to convey as accurate and intelligible a prognosis as possible to the lay mind, we express in percentages the prospect (*a*) of complete recovery, (*b*) of partial recovery, sufficient to allow the patient to resume his old work or some other employment, and (*c*), which applies only to those who are working, of continuing at the present work for a reasonable time.

---

[1] Being a paper read at a recent joint sessional meeting of the West of England Branch of the Society of Medical Officers of Health and the Royal Sanitary Institute.

Thus, in a slight case seen for the first time, one might well say "50 per cent. prospect of (*a*)"; in a worse case, when there seemed an even chance of a partial recovery, the prognosis would be "50 per cent. of (*b*)"; while in a working case, but with the health precarious and a breakdown possible at any moment, one might say "50 per cent. of (*c*)." Varying circumstances would, of course, raise or lower the percentage figures correspondingly. Now, in making our periodical returns to the county sanatorium about the condition of patients after discharge, this scheme is made use of and a number is placed against the patient's name as follows:—

Class 1.—Patient at work—90 per cent. prospect of (c) or more. (This may be considered a cure.).
„ 2.—Patient at work, but health somewhat uncertain—60-90 per cent. prospect of (*c*).
„ 3.—Working, but health precarious—40-60 per cent. of (*c*).
„ 4.—Too ill to work.
„ 5.—Very ill.

These numbers have been used in my classification of results. 1 and 2 I have bunched together, also 4 and 5, partly to simplify matters and partly to bring my results into line with other workers who classify patients as full work (1 and 2), part work (3), and no work (4 and 5).

A classification on the basis of "at work" or "not working" is not altogether satisfactory, as so much depends on the sort of work; a manual labourer may have to give in, whereas a clerk or artist, who is much worse, may easily continue at work. I have known a clerk in one case and a journalist in another who continued at work almost to the last. Such cases have been classed as (4) in one or two instances, even though the patient was working. Nearly every case is classified from a personal knowledge of his condition; once or twice only have I been satisfied with a postal inquiry; in a few more instances I have relied on a report from the patient's doctor or from relatives in a position to know. A postal inquiry is usually insufficient, a patient may report himself "very well" and yet be found on further investigation in Class (4).

The sanatorium cases were treated mostly at our County Sanatorium, but a good many elsewhere. The treatment adopted was modern sanatorium treatment—fresh air, good food, and graduated labour. Several different medical superintendents were concerned. The treatment of controls was for the most part advice only. Some continued for the whole period under their doctor, but the majority were only occasionally seen by him, and many not at all.[2] Not more than one or two had tuberculin treatment, a few had special treatment of different kinds such as I.K., and others tried patent remedies. I have never been angry or ceased observing a patient because he was under "Dr." Stevens or "Dr." Alabone; but it must here be said that for a tuberculosis officer to keep all patients under observation requires more tact and perseverance than to keep patients in private practice. Patients who left the sanatorium under a month are counted as controls; there are only a few of these.

Stages of disease.—Three stages are recognised: (1) slight; (2) medium; (3) extensive. Very few Stage 3 cases were sent by me to a sanatorium, but a good many are found among the controls, because all those of whatever stage are included who might *arguably* be considered as suitable for a sanatorium. I have cut out, on the one hand, moribund and bedridden cases, obviously too ill to be sent, and, on the other, cases of old arrested disease calling for no treatment. A special heading has not been made for patients with tubercle bacilli present in the sputum, for it is difficult to ensure a satisfactory report. The results are misleading unless a suitable specimen is examined carefully, and on several occasions, which can only be done properly in an institution with its own pathologist. All ages and both sexes are included.

Results.

The detailed results appear in the following tables. Of the 270 cases in all stages of disease, two years after sanatorium treatment 119 (44 per cent.) come under classes 1 and 2; 44 (17 per cent.) under 3; 71 (26 per cent.) were classed as 4 and 5; and 36 (13 per cent.) were dead. It will be generally agreed that these are good sanatorium figures.

It might be said that as there are only 15 of Stage 3 in the sanatorium series and 116 in the controls, that these cases should be eliminated from both series; this has been done in Table II. On the other hand, it might be urged that among the slight cases used as controls are several discovered as contacts, who might be considered by some observers as cases of pathological and not clinical tuberculosis; therefore Stage 2 cases in each series are similarly compared. Again, the sanatorium results are not bad.

TABLE I.—*Results After Sanatorium Treatment Compared with Cases Otherwise Treated. All Stages of Disease.*

—	1 and 2.	3.	4 and 5.	Dead.	Total
Sanatorium cases after two years	119 (44)*	44 (17)	71 (26)	36 (13)	270
Controls after two years ...	321 (54)	86 (14)	113 (19)	77 (13)	597
Sanatorium cases after four years	55 (46)	21 (17)	15 (12)	30 (25)	121
Controls after four years ...	139 (50)	30 (11)	40 (14)	73 (25)	282

TABLE II.—*Sanatorium Results Compared with Controls at the Same Stage of Disease.*

Sanatorium cases, Stages 1 and 2, after two years ...	118 (49)	42 (15)	64 (24)	31 (12)	255
Controls 1 and 2	316 (66)	69 (14)	63 (13)	33 (7)	481
Sanatorium, Stage 2, after two years	54 (35)	31 (20)	43 (28)	25 (17)	153
Controls 2	110 (44)	51 (20)	56 (23)	31 (13)	248
Sanatorium, Stage 1, after two years	64 (62)	11 (11)	21 (21)	6 (6)	102
Controls 1	206 (88)	18 (8)	7 (3)	2 (1)	233
Sanatorium, Stage 3, after two years	1 (6)	2 (13)	7 (49)	5 (32)	15
Controls 3	5 (4)	17 (14)	50 (43)	44 (39)	116
Sanatorium, Stages 1 and 2, after four years	55 (48)	21 (18)	13 (11)	26 (23)	115
Controls 1 and 2	139 (65)	20 (9)	26 (12)	31 (16)	216
Sanatorium, Stage 2, after four years	18 (30)	15 (25)	7 (11)	20 (34)	60
Controls 2	44 (43)	11 (11)	19 (19)	28 (27)	102
Sanatorium, Stage 1, after four years	37 (67)	6 (11)	6 (11)	6 (11)	55
Controls 1	95 (83)	9 (8)	7 (6)	3 (3)	114
Sanatorium, Stage 3, after four years	—	—	2 (33)	4 (67)	6

* Figures between parentheses are percentages.

TABLE III.—*Cures obtained in Sanatorium and Control Cases.*

—	Stage 1.			Stage 2.		
	Total.	Cures.	%	Total.	Cures.	%
Sanatorium cases after two years	102	30	30	153	9	6
Controls after two years	233	107	46	248	17	7
Sanatorium cases after four years	55	16	31	60	4	7
Controls after four years	144	62	54	102	10	10

We may now consider the number cured; only those coming under Class 1 (90 per cent. prospect of (*c*) or more) can justly be called cures. These are among the sanatorium Stage 1 cases after two years out of 102, 30 cures (30 per cent.); after four years, 16 out of 55 (31 per cent.). Among 233 Stage 1 controls after two years, 107 are counted cured (46 per cent.) and after four years 144 cases, 62 (54 per cent.). Among Stage 2 sanatorium cases, after two years, a total of 153 gives 9 cures (6 per cent.); and after four years, 60 cases, 4 cures (7 per cent.). Controls at Stage 2, 248 cases, after two years yield 17 cures (7 per cent.); and after four years, 102 cases, 10 cures (10 per cent.).

The stability of the percentage of cures after two and four years shows that this represents something definite. The majority of cases discharged from sanatorium with "disease arrested" relapse within a short time.[3]

---

[2] Some 12 to 15 were treated as dispensary out-patients by the assistant tuberculosis officer.

[3] Bardswell found that patients, at an average age of 33, discharged from Midhurst "arrested," had the same expectation of life as the average individual of 60, and those "much improved" the same as at 74!

A large number of patients reach Class 2 and there remain indefinitely, tuberculosis not defeated and yet not gaining ground, or gaining very slowly. There occurs in certain of these a race, so to speak, between tuberculosis and senility as the ultimate cause of death.

Discussion.

Believing, as most of us believe, that the sanatorium provides a useful method of treating tuberculosis, I should have preferred the figures to show a little bias in its favour, but the reverse is the case. Allowing a wide margin for error, and supposing that the error is all on one side, remembering also that patients who have been treated at home and have gone down hill are then sometimes sent to a sanatorium, it cannot even so be said that sanatorium results, at the end of two or four years, are in any way better than those obtained in patients who have not been there. If it had been a question of comparing my control figures with someone else's sanatorium figures, it might have been urged that the diagnosis was made differently, or that some such fundamental difference existed, but all these cases have been seen and classified by the same observer, and if errors of diagnosis have been made in one series so also in the other. Cases in which the diagnosis of tuberculosis seemed incorrect after further observation have been struck out of both series. Acute cases, with slight signs, but perhaps some fever and tachycardia, do not tell against the sanatorium, for they would not be sent until observed a little longer.

The patients here considered came from rural, semi-rural, or small urban districts, although frequently living under bad conditions; it would be interesting to learn the results of a similar investigation among a purely urban population. Moreover, my cases are drawn almost entirely from the poorer classes; I cannot speak of sanatorium results among well-to-do patients as the number of these observed personally is too small. True it is that not very much is claimed for the sanatorium nowadays as far as the individual patient is concerned; Newman emphasises this, and so does Bardswell, but Bardswell says also, "physicians of long and intimate experience of the disease are unanimous ...... that residence in a sanatorium represents the best treatment available at the present time." Some years ago a physician of just repute, and whose opinion I respect, told me that perhaps two out of ten early cases are cured or materially relieved by sanatorium treatment; I agreed with this observation at the time, but further experience has driven me to believe that even he over-estimated their value. Our ideas about sanatorium results are partly created by the appearance of patients on discharge (often only a masking of symptoms), and partly by a perusal of the reports from sanatoriums of the condition of patients on their discharge; a large number being reported as disease "arrested," a large number "much improved," with quite a small number stationary, and a very small number "worse."

It is acknowledged that the majority of patients leave a sanatorium stouter, and of better appearance in every way, than on admission; it is further generally acknowledged that the majority of these lose ground quickly on return to their old surroundings; but it is not, perhaps, recognised that they lose ground so rapidly that after two years they have frequently fallen below the level they would then have reached had they never been to a sanatorium. The reason is that the patient had become more or less adapted physically and mentally to fighting the disease under adverse conditions, but after a stay in a sanatorium he has lost this adaptation and may never regain it. Often enough sanatorium treatment is advised for patients who are continuing at work, although far from well. They go away and return after a few months, but never work again; whereas had they been left alone they might have continued the running fight indefinitely. If a tree growing feebly in a poor soil is transplanted to a good soil and then, after improvement, returned again to the bad soil it will not resume its feeble growth, but will probably die.

It is said that a longer period of sanatorium treatment would make all the difference, but this has still to be proved; certainly the patients who remained longest in my series did not give such good results as those who were there a short time; but this observation is hardly fair, for patients who are ill, but appear to be gradually picking up, are often kept a long time, while the slighter cases, who seem well, are sent out at the end of three months. Similarly, if I control sanatorium results by the results in patients treated with quack or special remedies (unluckily the figures are too small), the sanatorium comes out much better, but then patients often turn to these special remedies just when they are becoming hopelessly ill. Possibly if patients were kept at the institutions for a year or more we should then have our authorities urging for a period of three to five years instead of one.

Hitherto all sanatorium results have been published by medical superintendents or those concerned in various ways with sanatorium administration, whose views are often limited to the selected class of patients sent there, and who must, therefore, find it difficult to visualise tuberculosis as a whole. So much is the sanatorium considered to be the basis of all tuberculosis work that no tuberculosis officer is considered properly trained until he has worked there. Private practice might prove a better training ground. Retreating from the standpoint of physical benefit, it is often held that the educational value of a stay at a sanatorium is all-important and makes the patients do better afterwards; it is undoubtedly of great assistance to a patient to know something about the disease, and to recognise his own limitations, but still this does not seem to make his condition, after two years, compare favourably with a patient who has never been there. Probably, however, there is a real value in teaching a patient how to protect others from infection.

The Uses of a Sanatorium.

I do not for a moment advocate the scrapping of all sanatoriums, but the view that a sanatorium as at present conducted is a curative institution, contrasted with the tuberculosis hospital, used mainly for isolation purposes, must be abandoned, convenient though it was. The chief use of a sanatorium lies in prevention, for by this means a number of potential sources of infection are removed for a time from contact with the rest of the community. Moreover, a sanatorium is a kind of mission station, and it is partly to its influence that such an improvement in popular ideas of domestic hygiene has taken place in the last 20 years. A sanatorium with a tuberculosis colony attached has the advantage that it keeps patients away longer; time will show if it benefits the individuals. A place like Davos is the ideal tuberculosis colony. An isolated but busy health resort, with a few minor industries, peopled mainly by those who have active or arrested tuberculosis; shopkeepers, shop-assistants, bandsmen, waiters, and doctors, in this respect nearly all alike. I believe there are similar places in the United States, but we have none here, and it would naturally be difficult to build one up, if labelled from the beginning as a tuberculosis settlement.

Improved Sanatorium Methods.

Undeniably a few cases are definitely and permanently improved by sanatorium treatment and it is worth considering if this number can be increased by improved methods of treatment. First, it must be remembered that the success of a sanatorium depends more than anything else on the personality of the medical officer in charge (as, indeed, do most forms of treatment). Secondly, measures should be taken, especially in the winter months, to keep patients warm and comfortable. I know that Dr. Leonard Hill has shown experimentally that metabolism varies directly as the rate of cooling of the skin (in other words, man is a warm-blooded animal), but his subjects were healthy and probably robust. There must be a limit to the process; in any case a point will be reached at which the body ceases to react to cooling. This limit will surely vary in healthy individuals, and may conceivably be reached very soon in a patient enfeebled age or disease. Such a patient may need still, warm air rather than a cold wind. It may even be questioned if increased metabolism is invariably advantageous. And when the individual is stimulated to exercise in order to counteract chill, no doubt it is beneficial if he sends a full stream of healthy blood surging through his tissues; but if instead of healthy blood he sends a mixture of blood and toxins the effect may be different.

Some years ago I pointed out to our county medical officer that sanatorium results would be much improved by warmth, and added that this would be generally recognised within 20 years. "Why wait 20 years?" he replied. So a county conference was arranged at which we were to decide what measures for heating the rooms should be taken, when the Local Government Board said that they would not consent to heating, and the matter had to be dropped. I noticed recently, however, that the new Liverpool Sanatorium is heated throughout, apparently with permission of the Ministry of Health. It is conceivable that better results would be obtained in airy buildings erected on ordinary hotel lines. The majority of patients in Davos are treated in hotels. They have balconies where they can lie out during the day, but they can close up as they wish at night, and the rooms have a heating apparatus, while all dining- and sitting-rooms are comfortably warm—sometimes too warm for British tastes.

Another improvement would be to abolish systematic auto-inoculation as introduced by graduated labour, which is to-day the standard treatment at most sanatoriums. Its introduction was owed to an excellent piece of original work within the sanatorium orbit, but after prolonged trial it has failed to make good. It is uncertain if patients are benefited any more by auto-inoculation than by injecting tuberculin, a treatment now rarely used. I have never met anyone who was convinced that graduated labour had improved his results. It is mentally helpful, no doubt, the gradual increase in work gives the patient a sense of improvement, but this could surely be achieved by other means. I have been told that "the best part of graduated labour is absolute rest," and even in this matter it may be questioned if the rest need be so absolute, for a patient will exert himself more in a single fit of coughing than by feeding himself at meal times for a whole day. Then, again, more attention should be paid to the mental side of treatment. The importance of this has been recognised since the war, but there is a danger it will be forgotten again.

Selection of Cases.

Our view as to the real use of sanatoriums being altered, our conception of what case is suitable for treatment there must also be modified. Each case, of course, must be judged on its merits, but it hardly seems justifiable, in the light of the present investigation, to send every slight case of tuberculosis to a sanatorium as soon as diagnosed, which is the standard advice now given (all forms of treatment ask for early cases, and it is not surprising in view of how well most of them do with very little treatment of any kind). It would appear better to treat such a case at home, possibly after a short "change of air," then to consider sanatorium again if there is no improvement after three months or so. No case that seems to be improving at home should be sent to a sanatorium. On the whole, the case likely to do best there is one with high resistance (but not necessarily slight disease) just failing to hold his own in the face of adverse conditions of work and surroundings—a type doubtless commoner in urban districts than in Devon. For instance, there are tuberculous women living under slum conditions, with several children, who have, may be, never had a holiday since marriage, and these often pick up satisfactorily after the country holiday which a sanatorium affords.

Conclusion and Suggestions.

At a recent discussion I heard a sanatorium authority advise, as they so often do, a further increase in the umber of sanatorium beds. He even named 500,000 the ideal in this country. I take the view that fore any extension of the existing sanatorium accommodation is made the whole matter should be carefully reconsidered. No claim is made that the present study settles the problem; it is only an attempt to throw light from a new standpoint on this difficult matter. I do think, however, that we are too much hemmed in by tradition and authority in considering tuberculosis, and that the time has come for free-thinking in this respect if we are to progress.

The distinction has already been mentioned between the sanatorium to which patients are sent for their own benefit and the hospital whither advanced cases are sent for the benefit of others; the hospital seems the more useful institution, although there are far fewer hospital beds available and no prospect of more hospitals being built (many sanatoriums already combine the two functions). I suggest that steps be taken to modify sanatorium treatment with a view to improved results; also that certain sanatoriums should be reserved for isolation purposes, to which mainly cases with tubercle bacilli in the sputum should be sent, at whatever stage of disease; while others, which might be called preventoriums, should be reserved for slight cases and suspects, no patient being admitted there with tubercle bacilli in the sputum. At the preventorium a patient would stay only for a short time, say a month, under convalescent home conditions, while at the sanatorium he would stay indefinitely, the longer the better.

We are, indeed, drifting towards this state of affairs, for the mixing of cases, as it now exists in many sanatoriums, means that sooner or later early cases refuse to go and the sanatorium becomes in effect an isolation hospital.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

"IDIOPATHIC" DILATATION OF THE BLADDER AND URETERS.

BY STANLEY R. TATTERSALL, M.R.C.S., L.R.C.P.LOND.

THE term "idiopathic dilatation of the bladder" was used by S. G. Shattock[1] for those cases of dilatation occurring without any of the usual causes for this condition being found. The obscure nature of the ætiology of this class of case may be sufficient excuse for this brief record of an example.

A. E. T., aged 18, a turner's improver, when first seen gave the following history. Since May, 1919, he had suffered from attacks of vomiting in the morning (before breakfast). These had not been accompanied by pain or hæmatemesis. There had not been vomiting at other periods of the day, and he had been able to continue his work till August 8th. A week later he complained of sore-throat, diarrhœa, and vomiting, and was confined to bed. He came under observation on Sept. 1st, when he was markedly anæmic and drowsy. He did not at this time complain of any pain. On examination the aortic second sound was markedly accentuated and the peripheral arteries thickened. The blood pressure was 140-110 mm. Hg. There was neither œdema nor ascites. The urine was acid, and showed a heavy cloud of albumin on boiling. Pus, blood, and sugar were absent. A few granular casts were demonstrated on microscopical examination. There was no sign of organic disease of the central nervous system.

While under observation the vomiting continued, becoming more frequent and occurring at irregular times throughout the day. On Sept. 4th a complete blood count showed no abnormality beyond a moderate diminution in the number of red blood cells. On the 7th it was observed that there was slight enlargement of both parotid glands. On the 8th this was more evident, and accompanied by a tenderness on pressure, with rise of the evening temperature to 100·8° F. The parotid swelling gradually diminished, but his general condition deteriorated. The vomiting became more frequent, and on the 13th retention of urine developed. Until this time no complaint with regard to micturition had been made, and this retention required the use of a rubber catheter, which passed without any difficulty. The urine now contained 2 g. of albumin per litre, with a little blood. Lumbar puncture on this date showed the cerebro-spinal fluid to be clear and not under abnormal tension. There was no excess of cells; globulin was absent, and the Wassermann reaction was negative. On the 15th signs of œdema of the lungs were evident, and the patient died on the 16th. With the exception of the evening pyrexia on the 8th the temperature chart showed no departure from the normal.

---

[1] S. G. Shattock: Proc. Royal Society of Medicine, December, 1908 (numerous references to literature).

Necropsy (28 hours after death).—The body was that of a fairly well-nourished youth. The parotid regions showed slight swelling bilaterally. There was extensive marginal ulceration of the gums. The scrotum contained one testis. There was no phimosis.

Head and neck.—No macroscopic abnormalities of brain or meninges; a bilateral suppurative parotitis, with abscess formation in the left gland; larynx, trachea, and œsophagus were normal.

Thorax.—Pleural and pericardial cavities normal; lungs bulky, engorged, and very œdematous; heart showed moderate hypertrophy of left ventricle; cardiac valves all healthy; cardiac musculature appeared in good condition.

Abdomen.—Liver and spleen normal; left testis small and atrophic and lying in left iliac fossa: intestines empty and collapsed. On inspection of renal regions kidneys could not be located; adrenals, however, in usual position; kidneys found to be lying on alæ of sacrum, each organ between psoas magnus and vertebral column, and partly in abdomen and partly in pelvis. Psoas muscles did not arise from the vertebral column lower than the third lumbar vertebra, and in order to accommodate the ectopic kidneys were placed much further from the mid-line than is usual. Ureters short, situate entirely within cavity of true pelvis and markedly dilated, measuring about 3 cm. in circumference. Bladder distended and hypertrophied, containing about 18 oz. of clear urine with a high colour; no calculi. Dissection of prostatic urethra showed normal verumontanum without any enlargement of prostate. Kidneys small, showing marked lobulation; on section they were of a pale brown colour. No differentiation between cortex and medulla visible; the capsule was firmly adherent, leaving when stripped a rough pitted surface. As a whole the organ felt very firm and fibrous. Neither hydronephrosis nor dilatation of the pelvis.

Microscopical examination of the kidneys revealed a very advanced degree of chronic interstitial nephritis, the organs being converted practically into a mass of fibrous tissue. The penile urethra was not examined directly, but as micturition for the first 14 days was natural and unimpeded it would appear to exclude the existence of "valves" of the urethra. There was, as stated, no phimosis, and the easy passage of a soft rubber catheter would negative the suggestion of the existence of a stricture.

Hypertrophy of the bladder with dilatation of the ureters consequent upon obstruction of the urethra is well known, but several instances have been recorded of this combination without any such obstruction having been found.[2] A further item of interest in this case is the ectopic position of the kidneys. It would also appear to be distinctly unusual for dilatation of the ureters to occur to a marked degree without a corresponding involvement of the kidney.

A CIGARETTE-HOLDER IN THE LARYNX.

BY N. HAY BOLTON, M.D. EDIN.

THE following case, which was treated at the Shantung-road Hospital, Shanghai, is sufficiently uncommon to be worthy of record.

Loo Va Le, a Chinese boy, aged 10, was admitted to hospital on Jan. 10th with the history that four days previously he had been sucking a Chinese wire cigarette-holder and had suddenly "swallowed" it.

Examination.—The patient was somewhat breathless and cyanosed; his temperature was 102·4° F. and he could only speak in a whisper. With the laryngeal mirror he was found to have an infantile type of epiglottis, but it was just possible to see the upper end of the cigarette-holder, apparently tightly gripped between the false cords; the lumen of its tube evidently constituted all the available space through which he could breathe. The upper aperture of the larynx appeared to be very red and inflamed.

Operation.—I thought it might be possible to extract the foreign body from above, and so (having put the tracheotomy instruments on to boil) proceeded to cocainise the throat; but the patient becoming more cyanosed, he was placed on the table and tracheotomy was performed under chloroform anæsthesia. In opening the trachea I cut right down on the cigarette-holder, and by extending the incision downwards was able to get hold of the lower end and pull it gently down and out through the wound. I put the tracheotomy tube in place, but at this point the patient stopped breathing, and we had an anxious three or four minutes performing artificial respiration until normal breathing recommenced. I left the tracheotomy tube in place for 48 hours in order to give time for the traumatic laryngitis to subside, and then withdrew it. The temperature came down gradually until it reached normal on the sixth day after operation; the neck wound healed up perfectly and there were no chest symptoms.

After about 10 days the patient's voice began to acquire tone, and on leaving hospital 24 days after operation he could speak with a fairly clear but weak voice; the true cords, however, were still thickened and inflamed.

The cigarette-holder was 2½ in. long, ⅜ in. in diameter at the wider end, and ¼ in. in diameter at the narrow end; the lumen at the narrow end was barely ⅛ in. in diameter.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this subsection of the Royal Society of Medicine was held on March 1st, Mr. E. LAMING EVANS, the President, being in the chair.

Recurrent or Habitual Dislocation of the Shoulder-joint.

The PRESIDENT, in opening a discussion on this subject defined the condition as one in which a joint, after dislocation has occurred and has been reduced and has remained reduced, offers a subnormal resistance to redislocation, and, in fact, suffers repeated dislocations by slight force. The shoulder is by far the most common joint affected. This is accounted for by the fact that 50 per cent. of all dislocations occur in the shoulder, by the reduction by unskilled hands, by defective after-treatment, and by the normal anatomical structure of the joint and the damage inflicted by the initial injury. The pathological lesions were discussed in detail.

The following methods of treatment have been employed: (1) Palliative, by the use of appliances to limit the joint movements. (2) Physiological, by increasing the tone of muscle, tendon, and ligament. (3) By reefing operations upon the capsule: (*a*) plication; (*b*) excision and overlapping. (4) By repair of ruptured tendons and musculo-tendinous insertions. (5) By muscle transplantation. A fair trial of mechanical support and physiological toning should be tried first, as they have cured cases. Reefing operations had been followed by many successes and not a few failures. Muscle transplantation has been performed by detaching the posterior fibres of the deltoid, passing them forwards inside the neck of the humerus and fixing them in front. Opinions differ as to whether the graft retains its contractile power, or undergoes fibrous degeneration.

He showed the following case treated by this (Clairmont's) muscle transplantation operation:—

Major ——, aged 41 years. Left shoulder dislocated at football in 1899, and redislocated 19 times since. When seen in 1920 even sneezing would produce dislocation, which was always attended by much pain and required surgical assistance for reduction. The dislocation was subcoracoid. Clairmont's operation performed in August, 1920. The "quadrilateral space" is defined through an anterior incision, some fibres of the pectoral major and latissimus dorsi being divided. Through a posterior incision a strip of the deltoid, with its nerve and blood-supply intact, is separated and its insertion divided. Not more than a quarter of the deltoid should be used. The free end of the flap is passed forwards through the quadrilateral space and sutured to the anterior fibres of the deltoid in front. The tension on the graft must be sufficient, but not excessive. The shoulder was fixed for six weeks when active and passive movements were begun. The result has been satisfactory so far. He can go into a practice scrum and demonstrate to his pupils how to get the ball.

Mr. T. H. OPENSHAW showed a man, the subject of epilepsy, on whom he had operated first 15 years ago. The right shoulder had been "out" 50 times and the left 35 times. Dealing with the right shoulder, he tried injections of irritants—e.g., iodine, carbolic, &c.—on four occasions; he cut the pectoralis major and teres major, he plicated the capsule, he performed an arthrodesis, all of which gave only temporary, if any, benefit. Finally, he cut the subscapularis and this cured him. On the left he did an arthrodesis and later cut the subscapularis. The result was spoilt by a fall, which produced a traumatic dislocation, and the recurrent trouble returned; he had the shoulder out three times in ten days. A second arthrodesis cured him. He said he had operated on ten cases of this sort, doing nothing but divide the subscapularis, and all had been successful, and he knew of others treated in a similar manner with equal success.

---

[2] C. R. Box: Proc. Royal Society of Medicine February, 1909.

Mr. **A. H. TODD** referred to two cases upon which he had operated. He uses an abduction splint.

Mr. **W. ROWLEY BRISTOW** showed a case affecting both shoulders. He was an epileptic and each shoulder had dislocated 16 times. Both joints were operated upon by the Clairmont-Ehrlich method, the right in August, 1919, and the left in November, 1919. The result is that the right is perfect. He has bowled 34 overs in one game without bad result. The left shoulder has dislocated again some five or six times. The first was reduced by a doctor, but the others he reduced himself. He feels as if it comes partly out but not right out, and the pain is not so severe as formerly. He thinks abduction splint unnecessary, and doubts whether the graft really functionates as a muscle as it is passed through a rough space.

Mr. **A. W. SHEEN** showed a case, a male, aged 43, who dislocated the left shoulder in June, 1915. Redislocation had occurred 19 times since; sneezing had produced dislocation. When seen eight months ago movements, particularly abduction, were restricted. He had been treated by physical methods and now had a strong arm with full movement. There is some grating in the joint and X rays show some irregularity in the region of the greater tuberosity. There has been no redislocation for 14 months.

The **PRESIDENT**, in reply, said the discussion had brought out two good methods of treatment—viz., division of the subcapsularis (hitherto unpublished) and transplantation of muscle. He thought that abduction in the after-treatment, as suggested by Mr. Todd, might make the graft act as a lever to lift outwards the head of the humerus.

Recurrent Dislocation of the Patella.

Mr. **ROWLEY BRISTOW**, in opening a discussion on this subject, said the displacement was to the outer side. The two cases shown presented no sign of knock-knee, and the ligamentum patellæ did not seem to be elongated, and only one had quadriceps insufficiency. These three are given as the causes of the condition, but do not seem sufficient, as knock-knee and quadriceps insufficiency are extremely common yet dislocation of the patella is rare. He suggested anatomical causes, the ridge on the external condyle of the femur being at fault. Goldthwait describes the condition as peculiar to young girls and women. Both his (Mr. Bristow's) cases were in men.

Treatment.—Redevelopment of the vastus externus should be tried and may suffice. If operation becomes necessary, what should be done? 1. If knock-knee is present, correct it. 2. Pleating of capsule on the inner side seems bound to fail; Goldthwait's three cases treated by this method relapsed. 3. Shortening of quadriceps (Tubby) is not considered a sound method. 4. Transplantation of half or all of the patellar tendon to the inner side. 5. The operation performed in the two cases shown consisted in transplanting the tibial tubercle well to the inner side, and then driving an osteotome into the femur immediately behind the ridge on the outer condyle, levering this forward to make it more prominent. This position is maintained by the insertion of a small wedge of bone taken from the original site of the tibial tubercle. The capsule on the outer side is incised and left open. Fixation for five or six weeks in full extension, followed by physical treatment.

In both cases, operated upon about a year ago, the result is satisfactory. The first case dislocated his left patella jumping over trenches in March, 1917, since when he could not straighten the knee. He walked with the dislocation unreduced for two years. Operation as above, January, 1920. Result: no relapse. Movement: full extension to 80 degrees. Walks well. The second case had his left patella dislocated in 1915 by a kick from a horse. Recurrence on four or five occasions. It was sometimes reduced by the patient and sometimes by a friend. Operation as above, February, 1920. Result: no relapse. Full range of movement of joint. Tender on pressure over transplanted tubercle.

Mr. **O. L. ADDISON** showed a boy of 7 years. He had loose knee-caps for two years before operation. He fell wn when walking. It was first noticed three months ter a fall downstairs. Plaster had been applied for months. Vastus internus was very wasted. On ending knees 35 degrees there occurred complete dislocation of patella to outer side of condyle. ? poliomyelitis affecting mainly vastus internus. Operation: reef of inner side of capsule and gracilis tendon inserted through a slit in the patellar ligament. Apparatus limiting flexion worn for six months. There has been no relapse.

Mr. **A. H. TODD** showed a woman of 37 with recurrent dislocation of both patellæ. At 10 years she fell and hurt one knee. Recurrent trouble ever since, associated with attacks of synovitis. The other patella began luxating without obvious cause. No knock knee. Both patellæ can be luxated easily by manual pressure. Operation is advised.

The **PRESIDENT** showed a case of a man who had had synovitis after injury in September, 1917. The patella had dislocated on flexion ever since. The displacement begins at 30 degrees flexion and becomes suddenly complete at 60 degrees. Operation in May, 1920. The tubercle of the tibia was transplanted inwards to a bed prepared for it, and fixed with catgut. Result: no recurrence; extension of joint full; flexion to 80 degrees.

Mr. **H. A. T. FAIRBANK** had operated upon three such knees. He transplanted the tibial tubercle and overlapped the capsule on the inner side. In transplanting the tubercle he carried the incisions in the periosteum on either side of it down along the skin, and raised this strip of periosteum with the tubercle. This strip being left attached below, the continuity of the insertion of the quadriceps into the tibia was unbroken. In a child with habitual dislocation dating from birth, although there was no genu valgum when the knees were extended, there was definite valgus when the knees were flexed. Macewen's osteotomy was performed as well as the operation on the joint, and the result in both legs was entirely satisfactory when seen two and a half years later.

Mr. **ROWLEY BRISTOW** briefly replied.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on March 3rd, Professor **HENRY BRIGGS**, the President, being in the chair.

Dr. **H. RUSSELL ANDREWS** showed two specimens of

Sarcoma of the Uterus,

the first of which seemed to afford clear clinical evidence that a fibroid had become sarcomatous.

The patient, a single woman aged 65, for three months had complained of frequency of micturition, difficulty in emptying the bladder, and a sensation of pressure on the rectum, and had been losing weight. She looked rather cachetic. For two months she had noticed increase in the size of the abdomen; there had been no bleeding or discharge since the menopause. She had been told 12 years previously that she had a uterine fibroid, but she was never conscious of the presence of a tumour until ten days before she was seen by Dr. Andrews. Sir John Phillips wrote that six years previously there was a subserous fibroid, the size of an orange, not palpable per abdomen. Dr. Andrews found a very prominent, firm, rounded tumour rising out of the pelvis to a point two inches below the umbilicus. Vaginal examination was impossible. On rectal examination it was found that a good deal of the tumour lay in the pelvis and was almost fixed. The cervix was normal; the body of the uterus could not be differentiated. There was infiltration of the right utero-sacral ligament, and the diagnosis lay between sarcoma of the uterus and malignant ovarian tumour. During examination under anæsthesia the body of the uterus could be made out lying to the left of the tumour and blended with it. When the abdomen was opened hysterectomy was found to be impossible, so the right broad ligament was incised and the tumour shelled out, leaving the right cornu with tube and ovary on one side, and the rest of the uterus, which contained no other tumour, on the other side. There was much induration of the cellular tissue in the right side of the pelvis, and a large fixed gland on the right iliac vessels. The patient made a good recovery.

The description of the tumour from the pathological department of the London Hospital was as follows:—

An almost rounded tumour, partly fixed in formalin 15 × 13 × 10 cm. The outer surface shows rounded well-defined bosses, and is smooth except for fibrous tags. It appears to be encapsulated. There is one projecting nodule devoid of capsule. On section the tumour is divided into lobules that vary in size. These lobules have a homogeneous grey, brain-like appearance. A few of the lobules show a very faint whorling, with faintly differentiated translucent grey and pearly white bundles. Towards one end is a large area which is opaque and yellow. At one point on the surface of the growth there is a cord, 2·5 c.cm. long, of white tough tissue (growth) projecting from the surface. This is seen to project from a smooth lined, blood-stained tube, evidently a vein in the growth.

Dr. Andrews said that the naked-eye appearance of the tumour was characteristic of sarcoma. Mr. A. C. Palmer had supplied him with the following microscopical description:—

The section is taken from the most homogeneous portion of the tumour. The greater part of the section is occupied by atypical muscle tissue. In some areas bands of typical muscle fibre and connective tissue can be seen running through the section. In the atypical areas, muscle fibres are very abundant and they have their long axis disposed in all directions. Collagenous fibre is for the most part absent, but a few small areas of fine pink fibrils occur among the muscle fibres. The muscle nuclei vary greatly in size and shape, and multinucleate formations are frequent. In another section, taken from a portion of the tumour which showed faint whorling, there are numerous interlacing bands of pink collagenous fibre. In the spaces between the collagenous fibre, atypical muscle cells are relatively scanty.

In the second case, a necrotic sarcoma of the uterus, a large amount of the tumour, of jelly-like consistence, was discharged into the peritoneal cavity through a hole in the posterior surface of the uterus.

The patient, aged 51, had been married six months and had noticed her abdomen getting larger for 12 months. She had always suffered from menorrhagia, had had occasional floodings for a year, and almost continuous hæmorrhage for six months, often passing large clots. For two months she had noticed a lump protruding from the vagina, and for a week or two had had a foul discharge. She was profoundly anæmic, hæmoglobin 35 per cent., red blood corpuscles 1,900,000. On examination a hard, tender, rounded swelling was found which filled the lower part of the abdomen, reaching to just above the umbilicus. A necrotic, lobulated, pedunculated tumour the size of a large walnut protruded from the vulva, the pedicle being attached just behind the orifice of the urethra; the cervix was normal. The large tumour was evidently uterine; the vulval tumour was thought to be a sarcoma. There was a horribly offensive discharge. The vulval tumour was removed by Mr. S. G. Luker, and was first thought to be an inflamed, very œdematous fibromyoma, but on further examination proved to be a myosarcoma. The blood count improved slightly, but the foul discharge continued, the abdominal tumour became more tender, and the evening temperature varied from 99° to 101° F. It appeared probable that the tumour was undergoing necrosis, and as hysterectomy seemed dangerous Mr. Luker dilated the cervix and inserted two Carrel's tubes, through which the uterine cavity was irrigated with eusol. The temperature dropped and the odour of the discharge diminished. The tumour became smaller until it reached only two-thirds of the distance to the umbilicus, although no growth had been discharged into the vagina. Thirteen days after the insertion of the tubes hysterectomy was performed by Dr. Andrews after he had packed the uterine cavity with iodine gauze. In the peritoneal cavity was a quantity of soft, translucent, jelly-like material, inodorous, exuding from a hole in the posterior surface of the uterus. Glands along the common iliac vessels on the right side were enlarged. The wound healed well, but septic thrombosis ensued and the patient died four weeks later.

The pathological report was as follows:—

A uterus much enlarged, 14 × 11 × 4·5 cm. Peritoneum smooth throughout except for a soft red gelatinous nodule 1 cm. in diameter in right posterior wall of body. Uterus feels somewhat soft and doughy. The cavity is much distorted. In the right anterior wall, pushing the cavity to the left, is a large nodular mass which has broken through the endometrium. It is 9 cm. across and is made up of soft nodules, grey or greenish-brown in colour, separated by narrow sunken lines. The green nodules have a somewhat ulcerated surface. Others appear to be covered by endometrium. On section this mass consists of grey nodules, semi-translucent, and separated by narrow zones of white firmer tissue. The cut surface bulges slightly, and around the nodules in the wall are similar small areas. The mass is for the most part definitely encapsulated. There are other small masses raising the peritoneum on the posterior wall, some of which have hæmorrhage in them.

Microscopical section: (1) Œdematous, leio-myo-sarcoma of body of uterus; (2) cellular, atypical, œdematous fibromyoma; (3) normal uterine wall.

Dr. ANDREWS also showed a case of

Lipomatosis of the Stroma of a Uterine Fibromyoma.

The patient, a multipara, aged 38, had had menorrhagia since a miscarriage four or five years ago, and this had increased in severity during the last two years. The abdomen had been increasing in size for a year or more. For two months there had been swelling of the legs and puffiness of the face in the mornings. Patient was gravely anæmic, lemon-yellow in colour; Hb. 20 per cent., colour index 0·3, red corpuscles 3,100,000. The urine contained albumin but no casts. A large tumour, apparently a tense cyst, rose out of the pelvis to a point above the umbilicus. The cervix was almost out of reach, and a soft, apparently fluctuating swelling bulged deeply into the pelvis. The tumour was so soft that the resident thought at first that it was a distended bladder, and after passing a catheter that it was an ovarian cyst, whereas Dr. Andrews took it for a degenerate fibroid. After two and a half weeks, the patient's general condition having improved, Dr. Andrews performed subtotal hysterectomy, removing one enlarged ovary. The cavity of the uterus was enormously enlarged by a tumour 8 in. in diameter in the posterior wall. On section it was a mass of golden-yellow fat with a few white fibrous areas towards the centre. The patient made an uninterrupted recovery.

The following is a report of the tumour after it had shrunk:—

The tumour is rounded and as far as can be accurately measured is about 14 cm. in diameter. It lies in and occupies the posterior wall of the body. It bulges into the cavity and apparently fills it, the cavity being convex anteriorly and stretched over the tumour. The endometrium is smooth, grey, and thinned out over the tumour, slightly thicker elsewhere. Cavity 13 × 13 cm. Wall of uterus from 1·8 to 2·5 cm. thick. The cut surface of the tumour bulges and is bright yellow and translucent. Tumour is elastic and tough; it looks like lipomatous tissue. There are a few slits in it, and a few white fibrous areas towards its centre. It is everywhere enclosed by a thickness of at least 1 cm. of muscular tissue. Peritoneum smooth. No other nodules. Ovary 5·5 × 3 × 3 cm. It contains a few follicular cysts up to 1·5 × 1 cm.

Dr. Andrews anticipated some difference of opinion about the manner in which fat became deposited in this tumour. In some places the fat could be clearly seen to be in the connective tissue. In other places there were small groups of unaltered muscle fibres lying surrounded by fat. He personally would have been content to call the tumour a fibro-myo-lipoma of the uterus, but Professor H. Turnbull had said:—

"I should call the condition lipomatosis of the stroma of an intramural fibro-leio-myoma of the uterus. It is an example of fatty infiltration of fibrous tissue."

Mr. PALMER had supplied a description of the microscopical appearance of the tumour.

The section is taken from the centre of the tumour. The greater part of the section is occupied by lipomatous tissue. The fat is deposited as a large single globule which fills the cell. There are also areas and strands of tissue partly or completely free from fat cells. In these areas the muscle fibres are sparse and lie in a matrix which is, to a large extent, homogeneous and stained yellow, but contains delicate yellow and, less abundantly, pink fibrils. The appearances are those of an œdematous fibro-myoma. Very small areas of such œdematous fibro-myomatous tissue are seen between fat cells of the lipomatous tissue. Further, single muscle fibres or small groups of muscle fibres frequently lie between the fat cells of the lipomatous tissue. These appearances favour the view that it is the cells of the interstitial tissue that have become lipomatous cells.

Dr. CUTHBERT LOCKYER recalled a specimen from the London Hospital showing a similar condition of lipomatosis. There were about 12 cases on record and the point of interest lay in the doubtful origin of the condition. It might be a superimposed neoplasm or it might be a degenerative lesion. Dr. Lockyer had decided that the latter was more probable and that muscle cells shared in the degeneration.

Dr. HERBERT WILLIAMSON spoke of the paper published by him with Dr. R. St. L. Brockman.[1] His own specimen had shown a quite circumscribed tumour with a capsule in the centre of a fibro-myoma. He had been given an opportunity of examining the tumour described by Dr. Lockyer and he had found evidence of globules resting on the muscle but none within the muscle.

---

[1] THE LANCET, 1920, i., 873

Mr. Palmer agreed with Dr. Williamson on this point.

Dr. Andrews briefly replied.

Dr. Geoffrey Evans read a paper on the Study of the Condition of the Arteries in a Uterus removed 24 days after delivery.

Mr. Aleck Bourne read a paper on Puerperal Salpingo-peritonitis.

SECTION OF OTOLOGY.

A meeting of this section of the Royal Society of Medicine was held on Feb. 18th, with Sir Charles Ballance in the chair, when Dr. A. R. Friel read a paper on

Zinc Ionisation and Electrolysis in the Treatment of Chronic Otorrhœa.

He dealt in detail with the results of the ionisation of 217 ears. The outstanding fact was the rapidity with which the suppuration cleared up under the method, in many cases within 24 hours. Ionisation was also an aid to diagnosis. In six of the cases the application of the method did not result in the cessation of the discharge. These had granulations and polypi in addition to the ordinary septic discharge.

Sir James Dundas-Grant supported, from his own experience in the clinic in which Dr. Friel practised the method, all that the author claimed for it. The results seemed best and speediest in cases having a large central perforation rather than a marginal one, though under the ordinary treatment even these seemed to be very obstinate.—Dr. W. Salisbury-Sharpe, who brought some cases from the clinic of the Central London Throat and Ear Hospital, confirmed all that had been advanced by Dr. Friel. One of his unsuccessful cases had complete obstruction in both ears due to perichondritis; as the electrode was unable properly to penetrate the obstruction, improvement had only been temporary. Another case had obvious disease of the mastoid bone, with granulations and a profuse discharge.—Mr. W. Stuart-Low said he had used the method in cases in which there were granulations, but for these he had discontinued it and reverted to the employment of a very fine actual cautery, the results of which were very satisfactory.—Dr. Andrew Wylie spoke of the good and rapid results achieved by the method in some cases he sent to Dr. Salisbury Sharpe.—Dr. P. Watson-Williams said he had been disappointed in one or two cases for which he had tried the method, perhaps because of the presence of complications or some fault in the technique employed. He spoke of cases of old-standing infection of the upper end of the Eustachian tube, and asked how contact of the electrode with the diseased tissue could be ensured. In the light of the present paper he intended to give the plan a further trial.—Mr. Sydney Scott remarked that 17 years ago Mr. West and he used the method at St. Bartholomew's Hospital on the suggestion of the late Dr. Lewis Jones. It was discontinued because it did not succeed in complicated cases in which there were granulations, and because the cases in which it succeeded were those which did not need any surgical treatment at all. He asked whether the cases referred to by Dr. Friel and Dr. Salisbury-Sharpe had been previously examined bacteriologically.

Dr. Friel, in his reply, said the cases now described were not bacteriologically examined before treatment. The method was not intended for the remedy of any factor except sepsis which was accessible to the zinc solution. Granulations and polypi should be removed surgically before ionisation was applied.

Mr. W. M. Mollison described two cases of

Paralysis of Eye Muscles with Mastoiditis

in boys aged 12 and 10 respectively, in which paralysis of the eye muscles occurred in the course of mastoiditis; the first after operation for acute symptoms arising he course of chronic suppuration, in the second in course of simple acute mastoiditis. In the second lumbar puncture did not reveal increased pressure cerebro-spinal fluid. In the first case this fluid was under pressure and was slightly cloudy. Recovery was eventually complete in both. The symptoms in these cases suggested meningitis, and the evidence seemed to point to the eye paralyses being due to metastatic infection rather than to the spread of infection to the tip of the petrous bone, and so to the nerves as they cross to the wall of the cavernous sinus.

Mr. Arthur Hutchison narrated a case of somewhat analogous nature in a boy aged 7 years, though in this the termination was fatal. The trouble seemed to have started with measles. There was pain in the left ear and over the left eye and the temperature was 101°F. After paracentesis of the left tympanic membrane the pain ceased and the temperature became normal. A week later, however, a sudden rigor occurred, with a temperature of 102°. This was of only short duration. A fortnight later there was further ear discharge, with pain, and a squint developed. Mastoid operation revealed red inflamed bone, but no pus, except in the antrum and attic. Five days later the temperature was 103·8°, the pulse 148, the boy vomited three times, and the neck became stiff. Lumbar puncture showed turbid fluid under pressure, which yielded streptococci. Daily injection of antistreptococcal serum did not avert the fatal issue. A post-mortem examination was not allowed.

Mr. Hunter Tod discussed the cases. He said the reason paralysis of the external rectus occurred in cases of acute otorrhœa and mastoid disease was not yet clear, and until that was understood it was difficult to know what was the best line of treatment, and especially whether or not the dura mater should be opened. In his own practice he found cases of paralysis following mastoid disease had been very few. He related two or three. In the presence of sixth nerve paralysis lumbar puncture should be performed, and if a septic focus was discovered it should be removed, care being taken to remove the bone well over the tegmen tympani and the anterior portion of the petrous bone.—Mr. Stuart-Low referred to a case with seventh nerve paresis and sixth and third nerve paralysis simulating cerebellar abscess, which cleared up under increasing doses of potassium iodide.—Mr. W. C. Wilkinson thought most of the cases of the kind were of the pneumatic type. In one fatal case an abscess was found at the apex of the petrous bone, and a large collection of pus at the base of the skull.—The President related some cases in his practice, and said that when a pathogenic organism, such as streptococcus, could be grown from the milky cerebro-spinal fluid, the case usually proved fatal.—Mr. Scott said he looked upon sixth nerve paralysis in ear conditions as an indication of increased pressure of cerebro-spinal fluid. In some the fluid was full of organisms, but in others such were absent.

Epithelioma of Auricle.

Mr. Norman Patterson showed again a patient, a man, aged 67, from whom an epithelioma was removed from the auricle nine years ago by a very extensive operation on account of the widespread glandular involvement.—The President congratulated Mr. Patterson on the case.

Cirsoid Aneurysm Involving Temporal Bone and Neck.

Mr. Patterson also showed a case presenting this condition, in a woman, aged 46, on whom two operations had been performed for removal of polypus from the post-meatal wall, at which the hæmorrhage was very severe. She now had a pulsating expansile swelling in the left anterior triangle with a systolic thrill. Pressure on the common carotid stopped the pulsation. The polypus removed showed no signs of malignancy.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY.

PREVENTION OF TROPICAL DISEASES AND THE RESPONSIBILITY OF LONDON: PRESIDENTIAL ADDRESS.

A meeting of this section of the Royal Society of Medicine was held on Feb. 24th, when Sir Leonard Rogers, C.I.E., F.R.S., delivered the Presidential Address, taking as his subject the future of the study of tropical diseases, and the responsibility which lay upon London in that regard.

He commenced by stating that the claims upon medical attention of tropical diseases were being fully recognised in the pre-war period, especially in this country, inasmuch as a large number of the British population, for public or private reasons, pursue their careers in our dependencies, where only too often they are the prey of parasitic disorders of a tropical nature. The Section of Tropical Diseases and Parasitology of the Royal Society of Medicine, he said, had been started before the war, but full organisation had not been secured when the war arrived, rendering the work of the section imperative on account of the large number of medical men who were brought into contact with every variety of tropical and subtropical disease while serving with the navy and army. Sir Leonard Rogers pointed out that the research work done at the Calcutta Medical College, where he had been professor of pathology, and at the large hospital of 600 beds affiliated, had led to vast public benefit by the prevention of disease, as well as to the promotion of the spirit of research. He described the methods employed to make intelligent appeal to the Home and Indian Governments and to wealthy individuals for money to equip and support this work. Large contributions for the upkeep of the institutions, he said, had come from Indian rajahs and Indian merchants, while subsidies for scientific research had been received from English men and business firms as well, to mention two names, from Sir David Yule and Sir Dorab Tata, of Bombay. He proposed that London, the wealthiest city in the world, having before it the examples of Calcutta and Bombay abroad and Liverpool at home, and the stimulating actions of philanthropists like Mr. H. S. Wellcome and the late Sir Alfred Jones, should endow the London School of Tropical Medicine, so that research laboratories in British tropical countries could be founded in connexion with the school. He believed that the support of the Colonial Office would be forthcoming for such a movement, and suggested that the start should be made by obtaining annual contributions towards the support of research workers to proceed to certain British colonies. He considered that the colonial authorities should supply laboratories wherein the researches should be carried on, these being adjacent to the largest available hospital. The men to do the initial work should, he pointed out, be selected by a strong organising committee, and it was particularly important that their early choice should fall on the right man, as the first five years of work would be critical. This plan, he said, would eventually ensure that all important British tropical possessions would obtain permanent laboratories and the services of scientific workers whose efforts could be supplemented, in accordance with urgent or special need, by temporary workers sent out from the London School.

Sir Leonard Rogers concluded a highly sensible address as follows:—

"I trust I have made it quite clear that I am not criticising the earlier policy, which was doubtless correct in the first stages of the evolution of our home schools of tropical medicine, but I do wish to suggest, in the light of my long Indian experience, that the time has come for the further advance I have indicated. Indeed, I think this has been necessitated by the very success of recent researches in this field, including all the work done on dysenteries during the war, for now so many of the simpler problems have been solved the remaining problems of tropical medicine will require much more prolonged and detailed inquiries, including team-work, such as is being provided for in the Calcutta school, the liberal public support of which would serve as a stimulating example to London philanthropists, and especially to those whose firms or companies trade with tropical countries. Their young assistants have to live in such climates exposed to unnecessary dangers to their health from the lack of the safeguards provided by research laboratories, and I appeal to their employers for support for the proposals I have ventured to bring forward."

MEDICO-LEGAL SOCIETY.—A meeting of the society will be held at 11, Chandos-street, London, W., on Tuesday, March 15th, at 8.30 P.M., when a paper will be read by Sir John Collie on The Plaintiff: a Psychological Study.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

A MEETING of this society was held at 11, Chandos-street, London, W., on Feb. 18th, with Professor W. J. R. SIMPSON, the President, in the chair.

Some Observations on the Pathology of Relapsing Fever.

Lieutenant-Colonel J. C. KENNEDY, R.A.M.C., in his paper on this subject, prefaced a detailed account of the minute pathology found in a single case by alluding to relapsing fever as endemic in Mesopotamia, and the cause of much sickness, particularly amongst Indian troops of the Mesopotamian Expeditionary Force. Its seasonal incidence was most marked during the first quarter of the year 1918–19, the majority of cases occurring in March. The disease was certainly louse-borne, and the organism was either *Sp. obermeieri* or *Sp. carteri*. He referred to a variety probably conveyed by a tick, which was prevalent in Persia but not in Mesopotamia. Early in 1919 there were many cases at Bagdad with considerable mortality. Between October, 1918, and June, 1919, the total case mortality was 3·6 per cent. (British 6·5, Indian 4·5, local 2·5 per cent.). The cases presented marked cerebral symptoms, delirium, and coma—features in common with those recorded by recent writers, including Vandyke Carter. Colonel Kennedy had found but scanty reference to the pathology of the disease in text-books, and quoted from Mackie's review of the subject up to 1908, which failed to demonstrate any characteristic changes other than those of severe septicæmia, such as fatty degeneration of the heart muscles, enlargement of spleen and liver with necrotic areas due to infarction or local concentration of spirillar toxins, hæmorrhages not uncommonly, especially in the kidneys, some bronchitis, and patches of necrosis in the bone marrow possibly due to infarction. Spirilla were demonstrated in the tissues with difficulty, appearing in the blood-vessels and about the hæmorrhages. His own observations were derived from examination of material from a fatal case in an Arab coolie in the isolation hospital at Bagdad.

The patient, who was semi-conscious, showed spirilla in the blood, enlarged spleen, general purpuric rash, marked jaundice and debility, and he died on the day of admission after five days' illness. The autopsy was held 12 hours after death. On microscopical examination spirilla were found only in smears of the surface of brain and in sections of the cortex. The brain also showed much meningeal engorgement and to a less degree of the cortex, superficial cortical hæmorrhages, and small areas of round-celled infiltration under the pia-mater, extravasation of red cells into the perivascular spaces of the pia-arachnoid, proliferation of large mononuclear (endothelial) cells around the meningeal vessels. Much brown pigment, both amorphous and crystalline, was found free in the blood-vessels and spaces and in the large endothelial cells. These showed phagocytosis, particularly in the cerebellum. The liver was large, fatty, and, microscopically, showed cell destruction, round-celled infiltration, engorgement of intralobular capillaries, proliferation of large endothelial cells of Kupffer type, deposition of much pigment, and the presence of many round or oval bodies of uncertain nature. These occurred both free and within the vacuolated gland cells, together with pigment particles, similarly also within the endothelial cells, which showed proliferation and phagocytic power, as in the brain preparations. It was suggested that these "bodies" were either of a specific nature, possibly protozoal, or a phase in the degeneration of polynuclears, but so far neither of these views had been verified. The discovery of spirilla in small numbers in the post-mortem material of the case was limited to the brain surface, and superficial layers of the cortex as revealed by Levaditi's method. Many of them showed a terminal granule or spore-like body, which in his opinion probably provided the clue to the cycle of development of the spirillum responsible for the relapses of spirillar fever. The spleen was large and showed pigmentation, necrotic areas, and large endothelial cells. The condition of the enlarged kidneys and bone marrow added nothing further to what was already known and described, and, with the heart's blood, had failed to show presence of spirilla.

Dr. C. M. WENYON had had the opportunity of careful study of Colonel Kennedy's interesting preparations, and was of opinion that the "bodies" described were possibly degenerated leucocytes of unfamiliar appearance as the result of section in different planes.

point, he thought, could only be cleared up by a thorough examination of a number of serial sections. He regarded the marked endothelial cell proliferation and the phagocytic and wandering properties as in no way characteristic of spirillar fever alone, being a common feature in other infections.

Dr. S. A. **POWELL** spoke of his considerable experience of relapsing fever in Bombay in 1902, when he had carried out as many as 200 autopsies on natives dying of the disease, a number of them collapsing in the streets and being brought in dead, or escaping from hospital when delirious, wandering for miles into the country till finally dropping from sheer exhaustion. In such cases the diagnosis to be determined by post-mortem examination rested between plague and relapsing fever. Splash-like hæmorrhages over the various serous membranes were a common feature, and fatty degeneration of the liver and heart was most marked in cases which had relapsed. He had never found spirilla for longer than six hours post mortem; in fact, they usually disappeared from the circulation within a couple of hours. Past malarial attacks, he suggested, might explain the large amount of pigment found in the material examined by Colonel Kennedy.

Lieutenant-Colonel S. P. **JAMES** (I.M.S., retired) questioned the validity of the diagnosis of relapsing fever, and also regarded past malarial attacks as possibly accounting for the presence of pigment.

Surgeon Rear-Admiral P. W. **BASSETT-SMITH** disregarded pigment as characteristic of relapsing fever, and drew attention to the frequency with which pigment bodies were found in intense toxic infections such as malarial and blackwater fevers.

Dr. W. H. **WILLCOX** referred to his paper on Relapsing Fever in Mesopotamia in 1916–18, read before the Royal Society of Medicine in 1919. The case mortality among Arabs was 8 per cent., among Indians 1 per cent., but there was a negligible mortality among Europeans. Louse infection was the prevailing form of conveyance. At Miani there was a tick infection producing Miani fever, very similar to relapsing fever, which he had met with in North Persia, attacking particularly newcomers.

Dr. G. C. **LOW** inquired as to the number of autopsies on cases of relapsing fever Colonel Kennedy had performed, and alluded to the comparative frequency with which the endothelial cells and pigment were found in malarial infections.

Colonel **KENNEDY**, in his reply, owned that the large amount of pigment present in his case might have been due to past malarial attacks, but no malarial parasites had been found. He regarded the greater part of the pigment as due to relapsing fever, and the great endothelial reaction was, in his opinion, a striking feature. The inclusions of pigment seen in blackwater fever and toxic hæmorrhages were not the same as in relapsing fever. Dr. Powell's experiences bore out the observations of Vandyke Carter, fatty degeneration of organs being most marked in relapsing cases.

The **PRESIDENT** proposed a cordial vote of thanks to Colonel Kennedy for his paper, which he thought might eventually prove an important discovery in the pathology of relapsing fever.

Five Cases of Fasciolopsis Infection.

Dr. A. F. **COLE** (Ningpo, China), in a paper on this subject, alluded to the rarity of the infection, although the five cases he described by no means represented all the cases seen in the wards of the C.M.S. Hospital, Ningpo. From study of sections he had been unable to observe any important differences between the types *F. buskii, rathouisi*, and *goddardi*. He referred to the importance of examining the fresh fluke and to the errors which had arisen from attempting to classify the dead and degenerated fluke. As a result of his own observations he was inclined to believe that it had not been clearly shown that there was more than one species, *Fasciolopsis buskii*, in the part of the Che-kiang province where he had lived. As regards clinical facts, his five cases suggested that: (1) The parasites lived in the stomach, duodenum, and the first part of the intestine only; when found in the large bowel they were nearing the end of their existence. (2) Their ill-effects were not in the direction of blood destruction, but were produced by toxic absorption leading to secondary anæmia, dyspnœa, general œdema, ascites, and skin changes, but without directly causing fever. (3) No melæna had been noted, but diarrhœa was common though blood had been stated to have been passed, but the freshly passed fluke readily resembled blood-clot in a mass of fæces. (4) No cases were observed in infants or young children. This was due possibly to weaning being delayed to the third or fourth year. (5) Unless the parasites were expelled by art or accident the disease might prove fatal, but rapid recovery followed evacuation of the parasites, unless in the later stages of exhaustion. Reference was made to the importance of fæcal examination and re-examination for the characteristic fasciolopsis ova and to the marked motility exhibited by freshly passed flukes in many cases. He thought the epigastric discomfort and irregular diarrhœa might be due to migratory movements of the parasite within the bowel, the change of position being possibly brought about by the cuticular spines and the musculature of the flukes. The size of the flukes varied considerably, in one case ranging between 53·3 and 25·4 mm. in length, and 16 to 9 mm. wide. Courses of thymol amounting to 45 g. in three doses proved the most efficacious treatment.

Colonel **CLAYTON LANE** referred to the importance attached by Goddard to the unity of species of fasciolopsis, who also maintained that the subdivision into *F. buskii, F. cuspei*, and *F. goddardi* represented a series of gradations of type. The question of nomenclature was one of priority. *F. fülleborni*, larger and more oval in shape, met with in Calcutta showed no armature, but Leiper had found spines; he himself had found similar specimens in Assam. The fluke was capable of powerful blood sucking, and was difficult to distinguish in the fæces from blood-clot. The symptoms were largely due to massive infestation and the blood sucking exerted by the parasites with consequent loss of blood. Thymol rapidly caused disinfestation and amelioration of symptoms. He did not consider the symptoms of anæmia, emaciation, &c., as due to simultaneous infection by ankylostoma, as Goddard had only found 2·9 per cent. of fluke disease infected with ankylostomiasis.

Dr. **POWELL** was satisfied that *F. fülleborni* and *buskii* were distinct species; he had met with the five cases of fluke disease in India also infected with ankylostoma.

Dr. **COLE**, in reply, did not regard the differentiation into species as warranted. Professor H. B. Ward had described the species *F. goddardi*, but this was now repudiated by Goddard himself. Concurrent infection with ankylostoma he regarded as rare and could be excluded from his Case 729, in which a total of 485 flukes had been passed while under treatment during a period of two months. Fluke disease in India was undoubtedly very uncommon, and this was borne out by Sir Leonard Rogers, who had not met with any cases.

Dr. A. **CONNALL**, W.A.M.S., in a paper on the results of

Examination of Chrysops for Filaria in West Africa,

said that Sir Patrick Manson had first suggested *Chrysops dimidiata* as a possible carrier of *Loa loa*, and this suggestion Leiper had ascertained to be well founded. Dr. Connal's observations had been made in 1917 and a number of feeding experiments had been carried out in the Medical Research Institute at Lagos. No fewer than 2255 specimens of *C. dimidiata* and *C. silacea* had been dissected, work which had been almost entirely conducted by Mrs. Connall. The district was one heavily infested by mangrove flies and the natives showed heavy blood infection by embryos of *Loa loa*. In the course of the dissections of 2255 specimens of Chrysops, of 2006 *C. silacea*, 16 had been found infected, and of 249 *C. dimidiata* 6 were found infected with *Loa loa*. Examinations were also made of the monthly results of Chrysops infection. May and June, the wettest months, provided the heaviest incidence of infection.

The **PRESIDENT**, in praising the value of Dr. Connall's observations, paid tribute to the excellence of Mrs. Connall's work at the London School of Tropical Medicine.

Dr. **LOW** stated that the host of *F. loa*, though not yet proved, might probably be Chrysops. Feeding experiments were attended by very great difficulties from the necessity of raising the insect from the pupa owing to the uncertainty of obtaining an insect free from previous animal filarial infection. The geographical distribution of the fly and *F. loa* was very exact. Intermediary stages of filaria had been found in the muscles of Chrysops and not in the Malpighian tubes. The embryo of *F. loa* measured 1/16th inch in the proboscis of the fly, just as in the case of *F. bancrofti* and the mosquito.

TUBERCULOSIS SOCIETY.

A CLINICAL meeting was held at the Margaret-street Hospital for Consumption, London, W., on Feb. 28th, Dr. NATHAN RAW, M.P., the President, in the chair.

Dr. JOHN SORLEY showed a case of Bilateral Fibroid Phthisis in a girl aged 7, complicated by unusually extensive hairy pigmentary nævus, involving a large part of the trunk and thighs. This was followed by a demonstration of X ray plates of tuberculous cases.

Dr. WILLIAM GORDON (Exeter) read a paper on

Rain-bearing Winds and Tuberculosis.

The paper dealt in brief with the evidence in favour of two main contentions, that exposure to strong prevalent rain-bearing winds (1) increases the prevalence of phthisis, and (2) has an injurious effect on existing cases.

The starting-point of the observations was the fact that those rural sanitary districts of Devon which faced south and west—that is, with the aspect then considered ideal for a phthisis health resort—were just those which showed the highest death-rates from the disease. The influence of soil, rainfall, sanitation, and social conditions was excluded and the matter investigated further by taking a series of parishes classed as "sheltered" or "exposed," when it was found that the phthisis death-rate was much higher in the latter than in the former. To the obvious objection that small numbers tend to produce large exceptions to any law of incidence, could be opposed the fact that exceptions were so few as thereby only to increase the cogency of the law. In the Okehampton rural district the average death-rate in the exposed parishes was nearly five times as great as that in the sheltered, and the disproportion was equally striking in the Barnstaple district, results which have been confirmed recently by Dr. J. Brownlee. Equally decisive results were obtained in respect of the sheltered and exposed streets of Exeter. By applying to these investigations the principle of "the approximate isolation of influences," by which is denoted the systematic enumeration of all the known influences involved and their successive elimination as far as possible from the problem, Dr. Gordon considers that the rain-bearing prevalent winds have emerged from this severe test as one of the most powerful of all influences known to affect the death-rate from the disease. Corroboration of this view has come from Japan, the Sandwich Islands, the Falklands, the Faroe Islands, and Iceland. It explains, as nothing else can do, the exceptions and difficulties met with by other investigators who have endeavoured to account for the prevalence of phthisis on the basis of soil, geographical distribution, occupation, density of population, or other factors. Further, Delépine found, on mapping out the situation of 1524 farms which supplied Manchester with milk, that great differences existed with regard to the prevalence of bovine tuberculosis in them. Using the data so ascertained, the lecturer showed that tuberculosis was from twice to five times as prevalent in farms which were exposed, partially or fully, as in those which were similarly sheltered.

As to the influence of these winds on the course of the disease, evidence, though far from complete, is yet very suggestive. Records from sanatoriums in different localities, under varying conditions of wind and rain, in sheltered and exposed situations, and comparison of collective results are suggested as the lines on which future inquiry should run. Already, however, they point to such an influence being manifested, while as regards the average duration of fatal cases under the contrasted conditions it is found that a higher proportion of cases of shorter duration (short cases, those lasting 9 months or less; long, 15 months or more) occurred in the exposed areas and a higher proportion of longer duration in the sheltered areas. Somme has recently drawn attention to the evil effects of wind and rain on sanatorium patients in Norway, the number of those discharged as improved being lessened after exposure to a period of persistently bad weather. The limits of effective shelter may be approximately defined in terms that a ridge 100 ft. in height will afford effective shelter to half a mile of flat country level with its base and more or less shelter to nearly half a mile further.

Dr. CAMPBELL MCCLURE cited the fate which befell the establishment of an annexe for consumptive patients in connexion with the French Hospital at Brighton. Being on the sea-front, it had to be closed as the results were found to be bad. Transferred to more sheltered conditions at Hastings the results have been good. Moral—the sanatorium should not always be blamed for bad results.—Dr. H. A. ELLIS stated that he had, when at Middlesbrough, to stop sending his patients to Redcar and Saltburn on the Yorkshire coast as the results were so uniformly disastrous, due to the effect of the prevalent north-east wind. He suggested that Ceylon, with its two monsoons, would be an admirable locality for the study of the effects of the winds on phthisis.—Dr. JANE WALKER considered that the fact that the patients in the Norwegian sanatorium, alluded to by the lecturer, were allowed to struggle against driving rain during their walks should be discounted in estimating the evil effects of the treatment.—Dr. F. RUFENACHT WALTERS commented on the exhausting effects of walking against strong winds, and the carrying of wet clothing in the case of ambulant patients, and the tendency to keep windows closed in streets exposed to such winds.—Dr. HORACE WILSON, from personal experience of practice in the Isle of Man, stated that phthisis was much more prevalent south of a ridge which separates the island into two parts than north of it, the latter being more sheltered and protected from the prevailing winds.—Dr. SORLEY pointed out that, despite the continuance of prevailing winds, the death-rate from tuberculosis was rapidly decreasing, and probably the disease itself was also less prevalent nowadays, so that other factors must be involved.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

A MEETING was held on Feb. 17th, Dr. F. J. SADLER, the President, in the chair.

Dr. J. S. FAIRBAIRN (St. Thomas's Hospital) opened a discussion on the question

Does Midwifery Practice and Teaching Require Reformation on Physiological Lines?

He said that midwifery was an integral part of medicine, being part of the larger subject of reproduction, and the importance, so tardily recognised, of the care of the rising generation to the national health and welfare, has given it a new and enhanced value. The present-day tendency in medicine is to study disease from the physiological side and discover the earliest evidence of disturbed function, and this tendency ought also to be our attitude towards midwifery practice. Dr. Fairbairn pointed out that this had not been the case in the past, as shown by the neglect of the physiological feeding of the infant for the perfecting of substitute feeding, at which great success has been attained, but along non-physiological lines. Considering the application of physiology to the conduct of labour, Dr. Fairbairn said we had hitherto concentrated on the artificial termination of labour by instrumental aid; the attendant's biceps had been the substitute for the uterine muscle in cases of indifferent uterine action. We should not argue on the sterile question as to when and when not to use forceps and the factors that interfere with good uterine action. We should discuss how their use may be eliminated, forceps delivery being regarded as the result of a failure to secure normal and physiological parturition. The two factors to which most of the cases of delayed labour in otherwise normal cases could be ascribed were emotion and fatigue. The discussion should turn on suggestions as to how these factors could be avoided, and whether the use of sedative drugs to diminish sensitiveness and secure rest was less physiological than operative interference. Dr. Fairbairn concluded by a reference to the future of midwifery practice, to the respective spheres of the practitioner and the midwife, and to the training and teaching of students.

The PRESIDENT emphasised what the speaker had said as to the importance of controlling the emotional factors which tend to disturb labour.—Mr. MILES PHILLIPS considered the pathological aspect of labour as being the one most calling for practical attention.—Mr. W. W. KING also thought that labour, from the point of view of the practical obstetrician, was best regarded as pathological.—Dr. SAMSON MATHEWS and Dr. W. E. HOULBROOK also spoke.

Corrigendum.—In our last week's issue lines 9 and
top of first column of p. 488 should read "the total
might be anything from the *15 per cent.* given by S
Hale-White to over *30 per cent.*"

Reviews and Notices of Books.

EXOPHTHALMIC GOITRE AND ITS NON-SURGICAL TREATMENT.

By ISRAEL BRAM, M.D., Instructor in Clinical Medicine, Jefferson Medical College, Philadelphia; Physician on Visiting Staff of Philadelphia General Hospital. London: Henry Kimpton. 1921. Pp. 438. 32*s*.

THE author of this work says in his preface that although "many books have been written on exophthalmic goitre—some mediocre, others very valuable—but little, if any, thought or space is given to remedial measures which do not require the knife." He hopes, among other things, to convince the reader that exophthalmic goitre does not belong to the realm of surgery. The burden of the book is "the futility of surgery in the therapeusis of the disease." In Dr. Bram's opinion any improvement that may be noticed after operation is of short duration.

Dr. Bram has been neither generous nor just to surgeons, and has reviewed surgical treatment with bias. His indictment is founded on certain premisses which are at present too controversial to be admitted as a basis for argument, such as the mortality of the operation, which he considers to be higher than the stated 5 per cent., while other authorities contend that with suitable precautions and care in selecting cases the surgical mortality is practically nil. Moreover, the mortality of the disease, apart from operation, must be taken into account. To say that patients only die from exophthalmic goitre when non-surgical treatment is "too greatly postponed" is contrary to all experience. That "many patients succumb to immediate post-operative acute exacerbations of hyperthyroidism" is quite untrue for this country if it means to imply that many patients who survive the operation so succumb. Dr. Bram states that "recurrences of goitre and symptoms mean multiple operations with the attending dangers." It is true that more than one operation may be necessary to attain the best result. But this is not because there is a recurrence of the goitre, but because a sufficient amount of the gland has not been removed at the first or even the second operation. It really amounts to doing the operation in stages for greater safety, for there is less risk with the second operation than with the first. Another apprehension put out by Dr. Bram is that the patient, "hypersensitive to the extreme degree, may die of fear or worry over the operation or even by light infection following surgical procedures." This is seldom encountered in practice; any great fear or dread of the operation in the patient is a well-recognised contra-indication to operation. The meaning of Dr. Bram's statement that "the frequent presence of sugar in the urine is a contra-indication to surgical procedure" is not clear to us. Certainly, if there is evidence of diabetes operation is contra-indicated, but this is not common. The danger of death by status lymphaticus, so dreaded by him, can be avoided by employing local anæsthesia, and that of tetany as a sequela due to the removal of the parathyroid glands is sufficiently remote; an eminent surgeon has observed it only once in 700 cases. Injury to the recurrent laryngeal nerve directly through the operation or subsequently by pressure of scar tissue does, as Dr. Bram says, sometimes occur, but it does not lead to serious disability as only one cord is paralysed. Post-operative myxœdema is rare, and can be effectively treated with thyroid preparation. It is certainly less distressing to have myxœdema than Graves's disease. A loss of initiative to get well and a general disgust with life and the medical profession after operation have not been met with in our experience.

The author has conjured up a number of bogeys hich have no real substance, and his use of quotations ot always disingenuous. He says "far-sighted ons in all parts of the world are now becoming ical with regard to their accustomed method of treatment of this disease and are beginning to lag in enthusiasm with respect to surgical interference in exophthalmic goitre." He then quotes the following words from the writings of Mr. James Berry, whose reputation as a thyroid surgeon is world-wide.

> "Reviewing the whole subject of the operative treatment of exophthalmic goitre, it seems to me that it may reasonably be doubted whether surgical treatment is not on the whole worse than useless. ...... None of the operations that have hitherto been practised upon the gland, the thyroid vessels, or the sympathetic are free from risk. Actual proof that any of them actually cure the disease is at present wanting. The sympathetic operation, although it may, and probably does to a slight extent, diminish the exophthalmos, does not usually cure it completely, and may be followed by very serious results, such as inflammation of the eye and even blindness. The larger operations upon the gland itself, such as extirpation, are attended with so much danger as to make them undesirable. ...... With regard to ligature of the thyroid vessels, it still seems to me doubtful whether this proceeding is followed by cure sufficiently often to justify its performance."

These words are taken from Mr. Berry's treatise on "Diseases of the Thyroid Gland and their Surgical Treatment," published as long ago as 1901. This work is entered in the bibliography, but its date is omitted. Comment is needless. Since 1901 Mr. Berry's views have very much altered, as the author could have seen for himself had he referred to Mr. Berry's Lettsomian lectures,[1] or his review of the present position of surgical treatment of exophthalmic goitre.[2] Dr. Bram's account of surgical treatment is grossly incorrect as a representation of present day practice. He jumbles together all the various operations which have ever been suggested, and adds some which have never been even entertained, and gives the lot as specimens of what surgeons have been "doing in the past decade in different parts of the world and during moments in the career of the same surgeon." The recent discussions at the Royal Society of Medicine show how few of these operations are now used by surgeons.

We have quoted enough to show that Dr. Bram does not present fairly the pros and cons of surgical treatment of Graves's disease. Judgment must follow results, and while the time may come when exophthalmic goitre may be always successfully treated by medical means, surgical treatment at present affords in some cases better results than any other known treatment. The treatment which Dr. Bram himself favours has been in use for many years, and is what is known in the middle west of America as the Forcheimer treatment. It consists essentially in the administration of hydrobromide of quinine in 5 gr. doses three times a day. According to Dr. Bram it should be continued day after day for at least a year after all symptoms have disappeared, and so if a patient has already had the disease three years when the treatment is started, it will take three years more before a relative cure is effected. Dr. Bram combines the quinine with other remedies and gives 12 formulas for capsules, so that the practitioner can ring the changes during the long period of treatment. A little veronal may be added if there is nervousness; a little ergotin if vascular disturbance; a little iron or arsenic if anæmia; lecithin if debility, and so on. This persistent quinine treatment, combined as it is with other methods commonly employed, may, in some cases, be followed by a relative cure.

We do not in any way underrate the importance of medical treatment, and physicians are more or less agreed as to the lines on which this should be carried out. The basal metabolic tests increasingly used in this country as well as in America will serve to indicate the progress of the patient with an accuracy formerly unknown. Many cases get well under medical treatment only, and all cases should first have a fair trial of medical methods. It is agreed that everything should be done to put the patient on a higher plane of health. If Dr. Bram were to control his prejudices, cut out his redundancies, and thus compress the book to half its present size, he might still transform it into a useful handbook for the general practitioner, and we hope he will do so.

PHYSIOLOGICAL CHEMISTRY.

A Text-book and Manual for Students. Third edition. By ALBERT P. MATHEWS, Ph.D., Professor of Biochemistry, University of Cincinnati. London: Baillière, Tindall, and Cox. 1921. Illustrated. Pp. xiv. + 1154. 40*s.*

THIS new edition of Professor A. P. Mathews's well-known book on physiological chemistry is slightly disappointing, for it appears to be only a revised edition of the former work with a few additions, mostly in connexion with the practical section which forms the last 250 pages. Otherwise the main change is in the chapter on vitamines. This subject is developing so rapidly at present that it is scarcely possible to write an up-to-date account of it. It is a subject, too, about which so much has been written and spoken that the task of the author is all the more difficult. The various experiments and writings require the most careful sifting before we can arrive at the truth. Professor Mathews has, however, given a very lucid introduction to the subject. The practical portion is overloaded for the ordinary student, but of the utmost value to the honours or post-graduate student. It would have been a help if some distinction had been made in the type between elementary and advanced exercises. Among the small amount of new matter introduced we notice particularly the method of Dakin for separating the amino-acids, which is sure to be extensively tried by other workers in due course; also the formula by Kendall for thyroxin, the active principle of the thyroid gland.

The book can be thoroughly recommended. Professor Mathews is particular to present the real facts of a subject and omits or severely criticises unsupported theories. His chapter on blood coagulation is the best example of this. All the facts as observed by Wooldridge are carefully described, and it is explained how they represent the actual process. The author finds no use for the extravagant theories of the German workers to explain this complex phenomenon. In another edition all biochemists will wish Professor Mathews to give in a similar way the facts about immunity; here again theories are so interwoven with experimental data that it is almost impossible to ascertain the real position.

We can all understand what a laborious task it has been to write a large text-book and keep the whole of it up to date, especially in a subject like bio-chemistry, which is extending so rapidly in all directions. This text-book is really the only modern one actually written in our language, the others being translations, though we have numerous books on the practical part. Finally, we regret to see so many misprints.

CROWLEY'S HYGIENE OF SCHOOL LIFE.

Fourth edition, revised. By C. W. HUTT, M.A., M.D., D.P.H. London: Methuen and Co., Ltd. 1921. Pp. 450.

THE fact that within four years three editions of this work have been issued, is sufficient proof alike of the interest and importance attaching to the subject, and of the ability with which Dr. Hutt has met the need of a cheap and handy guide for the school medical inspector and administrator. The passing into law of Mr. Fisher's Education Act of 1918 has greatly widened the possible range of school medical activities, and Dr. Hutt has taken advantage of the present re-issue to introduce references to some of the most important questions arising out of this Act. The bearing of the new provisions on the employment of school children in wage-earning occupations is shortly discussed in Chapter XIV.; while among the appendices are reproduced the gist of the circulars issued by the Board of Education regarding the establishment of nursery schools and in connexion with the medical inspection of pupils in secondary and continuation schools. In view of the probability that most of the sections of the new Act will lie fallow for some time owing to the present need for rigid economy, no doubt Dr. Hutt has done well to restrict himself merely to indicating these possible extensions of the school doctor's work without discussing them in any detail in the text.

Brought thus up to date, the work remains the best handbook we possess at present for the use of the school medical inspector.

REGIONAL SURGERY.

De Ruyter und Kirchhoffs Kompendium des Speziellen Chirurgie. Neu bearbeitet von Dr. F. ERKES und Dr. B. O. PRIBRAM. Berlin: Karger and Co. 1921. Pp. 422.

THIS surgical vade-mecum is now in its fourteenth edition and has undergone considerable revision at the hands of its present editors. The 118 "illustrations" are all simple diagrams and help to elucidate the text, which is necessarily condensed. The book has evidently found a secure place in the category of "potted" works on surgery, though the index appears to us to be inadequate for a manual which must be primarily useful for purposes of rapid revision before examination.

SURGERY OF THE COLON.

La Chirurgia del Colon. By Professor ARISTIDE MATTOLI. Rome: War Office Stationery Department. 1920. Pp. 137.

THE author's series of 64 cases of operation on the colon forms the basis of this monograph. The operations are classified under 10 headings, one of the chief of which is, of course, colectomy. Professor Mattoli does not, however, practise this operation for intestinal stasis; his records show that for this condition he prefers appendicostomy, lateral anastomosis (transverso-sigmoid or cæco-sigmoid), or ileo-sigmoidostomy. The monograph forms a full and useful summary of the operative treatment of diseases of the colon.

THE HORTON WAR HOSPITAL.

The Story of the Horton (County of London) War Hospital, Epsom. By Lieutenant-Colonel J. R. LORD, C.B.E., M.B., Officer Commanding. London: W. Heinemann. 1920. With 7 plates and a plan. Pp. 264. 12*s.* 6*d.*

BEFORE the war Lieutenant-Colonel J. R. Lord was the medical superintendent of the Horton Asylum at Epsom, afterwards converted into a military hospital, and he has now compiled an interesting record of the work done there for sick and wounded soldiers. The first batch of patients arrived in May, 1915, and when the hospital closed in the autumn of 1919 some 45,000 patients of all ranks (including naval officers and men) had received treatment in the institution. The conversion of an asylum into a large military hospital necessarily involved difficulties; these were successfully overcome, and the book tells a story of services generously rendered to our wounded soldiers by all sorts of people. Any profits that may accrue from its sale will be devoted to the erection of a war memorial in the hospital chapel.

PERSONAL BEAUTY AND RACIAL BETTERMENT.

By KNIGHT DUNLAP, Professor of Experimental Psychology in the Johns Hopkins University. London: Henry Kimpton. 1920. Pp. 96. 6*s.*

IN the first part of this book the author maintains the vital importance of beauty to the race, and in the second part develops the theme that beauty should be conserved by the pursuit of certain ideals. To Professor Dunlap the main importance of marriage as an institution is its primary function of the procreation of children; the spirit of comradeship which arises between two people whose lives and interests are so closely interwoven does not impress him so strongly. He regards the common assumption that the maternal instinct is far stronger than the paternal as fallacious. The Greek ideal of physical beauty admired by Professor Dunlap is assuredly desirable, but beauty belongs not to form alone, and connotes other qualities which human betterment demands.

JOURNALS.

British Journal of Dermatology and Syphilis.—In the February number is an extended version of the Case of Human Glanders by Dr. F. H. Jacob and others which appeared in THE LANCET of Nov. 6th, 1920 (p. 941). The illustrations include an excellent coloured plate of the cutaneous lesions of the trunk. Professor H. M. Turnbull describes in great detail the different cells found in the inflammatory foci, and shows that, although the lesions resemble those caused by other pyogenic microbes, they differ in certain important particulars. Vascular lesions are conspicuous, and the inflammatory reaction is strictly vascular in its distribution. Further, the dense leucocytic infiltration is associated with great activity of the fixed tissue cells, which exhibit a high degree of phagocytic power. The giant cells, often described as characteristic elements in the glanders lesion, were, apparently, absent. It is remarkable that all attempts to isolate the infecting organism failed, and the diagnosis was only established by the demonstration in the lesions of organisms morphologically resembling the *Bacillus mallei* and the similarity of the inflammatory reactions to those occurring in cases of proven glanders, which is something of a triumph for the histologist. Pathologists will welcome this description by a recognised authority of this rare and most difficult type of inflammation.—In a brief article Professor C. Rasch, of Copenhagen, describes the effect of the sun's rays upon a syphilitic eruption in a girl of 19. Macules and papules, otherwise almost general, were absent on the upper part of the chest and back left uncovered by a low-cut blouse. He raises the general question of the value of insolation in the treatment of syphilis.

Journal of Industrial Hygiene. London: Macmillan and Co., Ltd. 30*s.* annually; single copies, 4*s.*—A series of articles dealing with the dust hazard in industry have recently appeared in this journal. The first, by Messrs. E. S. Longfellow and A. C. Fieldner, published in the September number, discussed the efficiency of the Palmer apparatus for determining dust in air. The method employed in this apparatus, which is being used extensively in the United States, is to wash the dust from a measured flow of air with a water spray. Two tests were applied: the first was the Tyndall light effect in which one stream of tobacco smoke, after passing through the Palmer apparatus, was admitted to a Tyndall box, while another stream passed directly into another box. Similar beams of light were passed through these boxes, and the proportion of pure air necessary to dilute the unfiltered smoke until the light effect was the same in the two boxes was determined. Only 13 per cent. of tobacco smoke was found to have been removed, while, when air containing finely divided silica dust was filtered, 30 per cent. of the dust disappeared. The second method was to weigh the dust retained from a dusty air sample in the Palmer apparatus and compare it with the weight of dust removed from a similar sample by the Cottrell method of electric precipitation. The Palmer apparatus retained about 45 per cent. by weight of the dust. Clearly the value of this apparatus is for comparative rather than for absolute determinations of the amount of dust present, and statements as to the dust content of air are unreliable unless the method of determination used is stated.

Two other articles by Dr. C. E. A. Winslow and L. Greenburg in January and February deal with industrial tuberculosis and the control of factory dust. These authors, when discussing the prevalence of phthisis in industry, are certainly in advance of some American authorities, since they appreciate the paramount influence of age-distribution when considering statistics; but they show a tendency to ascribe excess of phthisis in any industry to dust without considering whether dust capable of predisposing to phthisis exists in the industry. The argument goes in a circle; industrial phthisis is due to dust, therefore there must be dust; therefore the dust causes the phthisis. America will presently discover that there is not always harmful dust present, that some types of phthisis in industry have nothing to do with dust, and that the type caused by dust (silicosis) is always associated with other forms of pneumonoconiosis. At present there is much loose thinking and writing, for the most part based on Hoffman's unfortunate statistical data regarding mortality from respiratory diseases in dusty trades—a fair proportion of which are not dusty at all. We recommend to the writers the excellent summary of the position contained in the second Report of the Royal Commission on Metalliferous Mines and Quarries published in 1914, which seems to be quite unknown in the United States.

Their second article reports a valuable set of determinations made under comparative conditions as to number of particles and weight of dust found under various processes. The determinations were made with the Palmer apparatus; and the plea is put forward for standardisation, since weight alone is a fallacious guide; particles of a diameter greater than 10 microns cannot enter the pulmonary alveoli, and should not be considered. The number found per cubic foot of air varied from 7000 to 50,000 on different days in the country, reached 153,000 in city air, and 50,000,000 in an axe-grinding shop. The authors establish the value of efficient exhaust systems for dust removal, and show how a reduction in suction head in the exhaust ducts is quickly followed by an increase in air dustiness. Special attention was directed to protecting men employed in the unusually dusty process of sand-blasting; and the method employed in this country of protecting the worker by a helmet into which a supply of fresh air is driven was found to give an efficiency only slightly increased by the additional use of a respirator. The authors suggest as a practical standard that the dust in the air of workshops should be kept down to an average of 0·03 mg. per cubic foot of air and should never exceed 0·06 mg.; and, further, that such dust content of the air should be kept under a maximum of 300,000 one-fourth standard unit (1/10 micron) particles per cubic foot, and should not average over 200,000 particles. This paper is of considerable interest.

Another article worthy of note, by J. P. Baumberger and E. G. Martin, on Fatigue and Efficiency of Smokers in a Strenuous Mental Occupation, appeared in the October number. Definite results were obtained by no means favourable to the use of tobacco. Telegraph operators were observed; heavy smokers failed to maintain the level set by light smokers, they exhibited a lessened ability to sustain output to the end of the working day and a diminished capacity for reacting by increased effort to an increase in volume of business. But somewhat unexpectedly the heavy smokers showed a better output during the first hours of the day, although not nearly enough to compensate for their lowered efficiency toward the close of the day. The subject of fatigue also receives attention in the January issue, which contains a reply by Josephine Goldmark and Mary Hopkins to a criticism of Dr. Drinker's on their report upon comparison of an eight-hour plant and a ten-hour plant.[1] The reviewer had expressed greater appreciation of the pioneer work done by the Health of Munition Workers Committee in this country than of the American report. The reply, while not entirely convincing, makes out a good case for reconsideration; but we regret to find no attempt made to answer the criticism which appeared last August in THE LANCET upon this report. Here we would again emphasise that we find again and again writers in this Anglo-American journal apparently quite unaware of work carried out on this side of the Atlantic; surely the British editors ought to keep the contributors better up to date.

Closely associated with the subject of fatigue is an article by D. S. Gates, which appeared in December, on a Statistical Study of Accidents in Certain Textile Mills. Accidents were found at a maximum at 9 A.M. and 3 P.M., and appeared to be influenced by high speed of work rather than fatigue. Youths, aged 18 years, sustained the greatest number of accidents. Males had nearly twice as many accidents in proportion to their numbers as females; but they undertook processes with greater accident risk. Certain overseers were found with an undue proportion of accidents among their groups of operatives, the excess depending on the risk of the processes. Mr. Gates's paper, although not establishing any new underlying factor in accident causation, is an excellent example of the way in which any industrial concern may ascertain by simple investigation where accidents are occurring and why. The engineer thereby is guided in his work to important points.

One of the most important of recent articles was contained in the December issue on Experimental Trinitrotoluene (T.N.T.) Poisoning, by Dr. S. R. Haythorn. This article summarises the experimental work done in America on this question and its appearance fortunately synchronises with that of the recent report of the Medical Research Council on T.N.T. poisoning and the fate of T.N.T. in the animal body. Dr. Haythorn experienced the same difficulty as British workers in obtaining typical pathological lesions in animals. Nevertheless, his experiments led him to conclude that the respiratory tract, through the inhalation of T.N.T. in the form of fumes or dust, was negligible as a portal of entry for the poison; on the other hand, both the skin and the alimentary tract appeared important. Feeding was the form of administration adopted; and 19 out of 28 guinea-pigs exhibited liver lesions, but only one instance could justly be called acute yellow atrophy. Simultaneous administration of alcohol had no effect on the progress of toxic symptoms. Although toxic jaundice was difficult to obtain, severe anæmia, not unlike aplastic anæmia as seen in human beings, was readily produced in guinea-pigs. The author details the result of examining the various organs of the body, laying stress upon blood changes. His summary is:—

> "The chief factors leading to the terminal pathological findings appeared to be hæmolysis, probably associated with the formation of methæmoglobin, hypersecretion of bile, general asphyxiation of all tissues, direct toxic action of T.N.T. on the liver, bone-marrow hyperplasia, and final failure of kidney function."

This paper, which contains a useful bibliography, is a valuable contribution to knowledge of T.N.T. poisoning.

THE LANCET.

LONDON: SATURDAY, MARCH 12, 1921.

The Dangerous Drugs Act and the Draft Regulations.

THE Dangerous Drugs Act, it will be remembered, was the outcome of an International Conference, when it was agreed that measures should be taken to limit and control the distribution of certain dangerous drugs. Primarily, this limitation was intended to check the sale and exportation of these drugs to nations where, it was alleged, grave physical deterioration was resulting from their employment. Recent events, however, appeared to indicate that it was necessary for restrictions upon the distribution in the British Empire to be made more stringent, in spite of the protection given by the Poisons and Pharmacy Act of 1908, with the Schedule attached thereto, which together had hitherto been deemed sufficient safeguards. Hence the scope of the Draft Regulations under the Dangerous Drugs Act was extended, and although several versions have appeared in the press,[1] we believe the final form is not yet ready to be placed before Parliament. It is to be regretted that these Draft Regulations have not been more sympathetically received. They have been made almost a party question, and instead of being greeted by serious attempts to improve them or to seek to understand their scope and their effect both on the medical profession and on the dispensing chemist, a chorus of condemnation has occurred which may gravely imperil the working of a valuable Act.

The insufficiency of the powers claimed under the Pharmacy Act scarcely needs demonstration. That they have not led to the genuine control of the distribution of such drugs as morphine and cocaine has been shown again and again in the published records of cases of poisoning. Numerous fatalities have indicated that the existing regulations have been interpreted with great laxity. In a fairly recent case it was evident that although the inordinate quantity of the drug supplied might have caused suspicion, no steps were taken to question the validity of the prescription, which purported to be written by a doctor, but was suspected to be a forgery. While the dispensing chemist is undoubtedly the individual who is primarily affected by any regulations under the Dangerous Drugs Act, it must be remembered that, in his business, he has in past times been the chief agent for the distribution of drugs connected with the so-called drug habit. It is only comparatively recently that in this connexion morphine has been largely replaced by cocaine or by derivatives of morphine or cocaine, and an illicit traffic in these drugs has given rise to numerous prosecutions outside the ordinary channels through which they might have been expected to enter this country.

Any regulations to check the importation, the possession, and the unauthorised employment of these drugs, must be wide enough in scope and yet sufficiently detailed to cause a certain respect for the law, and for the penalties entailed through reckless carelessness or disobedience. When the Draft Regulations have passed through a process of adjustment they will not, we believe, be found irksome to the medical prescriber in private or in hospital work. They have been misrepresented by persons with imperfect acquaintance with their details, or by persons who prefer that the past conditions, with all their risks, should be maintained. As will be seen from our Parliamentary report, the Home Secretary has offered to exempt medical prescriptions containing narcotics from revelation of contents, and to meet the difficulties of the dispensing doctor. Further consultation with doctors, dentists, pharmacists, and veterinarians should ensure the removal of hardships, and to this end a watching committee of Members of Parliament has been appointed.

◆

Bilharziasis and its Treatment.

THE article by Professor H. B. DAY in this issue of THE LANCET, dealing with the treatment of bilharziasis in Egypt upon an extensive organised basis, constitutes another landmark in the therapeutics of a widespread and distressing malady. We note that an analysis of this large series of cases—one thousand in all—confirms the specificity of antimony tartrate for bilharziasis by the intravenous route, a method introduced by Dr. J. B. CHRISTOPHERSON in Khartoum and published in a series of papers in this journal over two years ago. An interesting addition is made to the series to-day, in which Dr. CHRISTOPHERSON sums up his experience upon the intravenous injection of antimony tartrate in the range of conditions for which it is appropriate. Meanwhile, during the last year the treatment of bilharziasis has been organised on an extensive scale in the Kasr-el-Aini Hospital, Cairo. Intravenous injections of antimony tartrate are now given as a routine method of treatment in the out-patient department. That no untoward symptoms have been noted and that this method has been successful in curing the majority of disease would indicate that the toxic effects of antimony, when properly given, have been somewhat overestimated, for we learn that the majority of patients returned to work immediately after treatment. Although the number so far treated has been comparatively large, and although the system instituted at Kasr-el-Aini is to be expanded throughout other parts of the Delta, Professor DAY holds out no hope that this disease will be extirpated from Egypt by any such curative measures. The proportion of the population infected with bilharziasis in one form or another is so high and the chances of reinfection in such an agricultural population so great, added to the fact that rats and other lower animals are susceptible to infection, that there is little possibility of banishing the disease, save by a combination of vigorous sanitary measures directed against the intermediary hosts of the parasite, together with wholesale intravenous therapy.

In treating the Egyptian fellaheen in the out-patient department Professor DAY and his colleagues were bound to encounter many difficulties arising from various causes. We learn that one-third of the patients ceased attending after one to three visits; 313 received less than 5 gr., only one-quarter of the total more than 15 grs. Directly amelioration of their more urgent symptoms sets in—that is to say when the activities of the bilharzia parasites are but temporarily suspended—patients would cease to attend. In order to achieve a permanent cure at least 13 gr. of antimony tartrate are necessary, though still larger amounts are desirable; only 19 cases of the series received more than 30 gr. As CHRISTOPHERSON originally pointed out, the effect of the antimony is primarily exerted upon the ova themselves, and they become shrivelled and blackened. Upon the parent trematodes the action of the drug is cumulative, and does not take effect till a total of 9 gr. has been administered. Treatment must be continuous, for if interrupted for any length of time the parasites are given a chance of recovery from the primary intoxication. For an adult daily injections of 1 to 2 gr. are advocated during the first week, followed during the second and third by 2-gr. injections given on alternate days. Antimony tartrate has the same effect upon intestinal bilharziasis—that is to say, upon *Schistosoma mansoni*—as it has upon the vesical disease caused by *S. hæmatobium*. The drug has been given in a more concentrated form than has hitherto been customary with perfect safety—that is, in a strength of 6 per cent. (1 gr. to water 1 c.cm.). Emetine also appears to be toxic to the bilharzia parasites, as has been claimed by DIAMANTIS and ERIAN; it is indicated more particularly in the infantile form, but more exact observations are required before this point can be settled. It has been suggested that it may exert a deleterious effect upon the ova but not upon the adult trematodes. At any rate there is little probability of this drug supplanting antimony tartrate in the routine treatment of this disease, as the cost of emetine injections on a large scale would be prohibitive. Intramuscular injections of colloidal antimony are said to have given encouraging results, and the advantages of the intramuscular over the intravenous route of injecting antimony in out-patient practice are so obvious in dealing with an illiterate population as to need no further comment. At present, however, this method is not likely to be utilised on a large scale, these preparations being unstable in the tropics and their cost is considerable. It will be interesting to learn whether the first favourable impressions of this preparation will be borne out by further experience. A few of Professor DAY'S cases suffered from a coincident infection with *Filaria bancrofti*, and it is stated that a temporary diminution in the numbers of circulating filarial embryos was noted after the antimony injections. A considerable amount of caution should be observed in attributing the fluctuations to any direct effect of the drug upon the embryos; as has been pointed out by Dr. G. C. LOW in recent numbers of THE LANCET,[1] unaccountable variation is commonly noted in untreated cases of filariasis. Therefore the claim of Sir LEONARD ROGERS that antimony tartrate is lethal to some extent to microfilariæ, rests at present upon a rather insecure foundation. It may be, as Dr. CHRISTOPHERSON suggests, that their sheaths are quite impermeable to the drug.

---

[1] THE LANCET, Jan. 15th, p. 134.

We are glad to note that the Ministry of Pensions are applying the lessons gained in the Soudan and Egypt to sufferers from this hitherto intractable disease amongst ex-Service men in this country. We understand that the majority of recent infec·ns—that is to say, men infected with bilharziasis ing the recent war—have so far been effectively treated and cured in the special clinic established under Dr. CHRISTOPHERSON, from which some of the records in his present article have come, but there is no reason why the 500 or so ex-soldiers who are still in receipt of disability allowance on account of this disease should not largely disappear from the pensions list. We understand that a considerable number in receipt of pensions still await treatment. The ruling of the Ministry appears to be that only those who contracted the disease during the recent war, or those originally infected previous to 1914 whose condition has been aggravated by recent war service, are entitled to receive free treatment, together with allowances and the other benefits bestowed upon disabled soldiers. There remains, however, quite an appreciable number of pre-war cases, dating in some instances from the South African War or attributable to service in Egypt or South Africa at some time previous to 1914, who are precluded from benfiting under the scheme. These men, in the present circumstances, cannot possibly afford treatment at their own expense, and consequently they must continue to draw their pensions, to the ultimate disadvantage of themselves and at the expense of the tax-payer. If any rule precluding a body of deserving men from treatment exists, we would recommend its reconsideration in order that these equally meritorious cases should receive the benefits of the antimony treatment. The matter is a humanitarian as well as an economic one. A sum estimated at some £10,000 per annum is at stake, and we suggest this could be saved.

◆

Personal Precautions against Encephalitis Lethargica.

THE Memorandum[1] on encephalitis lethargica issued by the Ministry of Health concludes with a clear statement of the precautions which it is advisable for the individual to take against infection:—

> The other occupants of a house in which a case of encephalitis has occurred or is being treated may be assured that the disease is one of low infectivity, and that very little risk is run by association with the patient. At the same time it is desirable that such association should be limited to what is necessary for proper care and nursing, and the patient should be well isolated in a separate room.
>
> School-children *in the affected household* may be kept from school, as a precautionary measure, for three weeks after the isolation of the patient. There is no necessity to place restriction on the movements of other occupants provided they are frequently examined and remain well. Those in contact with the case, however, should be advised to use antiseptic nasal sprays or douches, and to gargle the throat with solutions such as those advised for influenza.
>
> For example, any of the following may be used: (1) 1 per cent. solution of peroxide of hydrogen; (2) a solution of permanganate of potash, 1 in 5000, in 0·8 per cent. solution of chloride of sodium (common salt); (3) liquor sodæ chlorinatæ, 0·5 per cent. These solutions can be used as ordinary throat gargles or snuffed up the nostrils, or applied by an efficient spray.
>
> It is desirable that any persons in the infected household who suffer from sore-throat or other symptoms suggesting an abortive attack should be treated from this point of view and isolated as far as possible until they have recovered. The sick room should be thoroughly cleansed and disinfected at the end of the illness.

[1] Memo. 45/Med. H.M. Stationery Office

Annotations.

"Ne quid nimis."

INSURANCE MEDICAL RECORDS.

IN the House of Commons on Monday last a categorical question was put to Dr. Addison concerning the insurance medical records. He was asked whether he had received any complaints regarding the new form of medical card under the National Health Insurance scheme; whether he was aware that objection was taken to the new card on the ground that it was too inquisitorial; and whether he would give this objection his consideration. To this question Dr. Addison replied that the number of complaints which he had received about the insurance medical records was quite insignificant, consisting of representations from five out of 10,000 Approved Societies and branches, none from any of the insurance committees, and nine, mainly on points of detail, out of the 150 panel committees representing the medical men on the panel. The card, he said, was in substitution for two others used since the commencement of the Act, and had been designed mainly to give to insured patients the advantages enjoyed by private patients in those practices where doctors kept records, and were thereby enabled to be guided in treating current symptoms by reference to the patient's previous medical history.

To a further question he repudiated having invented the form of record card, or rather the revisions of the card, putting the responsibility on a Committee consisting solely of members of the medical profession—a large percentage of them being men in insurance practice. The accuracy of the latter reply has since been challenged on the grounds that there are three lay civil servants on the Committee, that the card was not designed wholly by doctors, and that 17 or 18 per cent. of panel doctors on the Committee could not be called a large percentage. The gist of Dr. Addison's reply should do away with the contentions in the lay press that the medical profession is seething with discontent—as we have read in one quarter; and that many thousands of protests have been formally registered—as we have read in another. There is a certain amount of dissatisfaction, as our readers know, but there has been no reflection whatever of such a large agitation in the medical journals, where the improvement of public health, the advance of science, and the maintenance of a right professional status form the single programme for advocacy; and the inference is that this story of wide disapproval has its origin in, or is supported by, political partisanship. When the Ministry of Health came into being, as the result of unanimous feeling that the institution of such a State Department had been too long delayed, medical men hoped that on questions of public health the party politician would be content to subordinate his views to the general good. That was sanguine, but even now the hope is alive with some of us. Undoubtedly the early work of the Ministry of Health has been hampered by complaints based upon ignorance of medical affairs, but in Medicine the truth sooner or later always emerges from misrepresentation. We are not asking, because the Ministry of Health is concerned with medical interests, that its sayings and its doings should be regarded as without the pale of public judgment; nor can we be blind to the fact that every Ministry of Health must be associated with a Government, when the party politician will assuredly attack it, if by so doing that Government can be discredited. But we are urging that such attacks should be taken at their value, when they will not be found to damage the public health more than temporarily.

REINFECTION IN SYPHILIS.

ACCORDING to Dr. Charles Mallory Williams, associate professor of dermatology at the Post-Graduate Medical School, New York, who records an illustrative case, the improvement in the treatment of syphilis during the last ten years has been accompanied by a great increase in the number of reported and apparently authentic cases of reinfection. Benario, who collected 96 cases from the literature in 1914, laid down the following requirements to establish a diagnosis of reinfection: (1) a positive clinical diagnosis of the primary lesion; (2) demonstration of *Spirochæta pallida*; (3) satellite adenopathy: (4) repeated performance of the Wassermann reaction; and (5), if possible, recognition of the source of infection. Forty-one of Benario's cases satisfied these requirements, and of the remainder 13 were probable and 28 possible examples of reinfection. White in 1917 in a series of 10,500 cases of syphilis, observed ten instances of reinfection, the diagnosis of which was based on the following grounds: (1) in the first attack spirochætes were found in the chancre or in syphilitic lesions, or the blood gave a positive Wassermann reaction; (2) in the second attack the spirochætes were found in a new chancre, which appeared at a site different from that of the first chancre, the blood at the same time giving a negative Wassermann reaction. In the cases reported by Dr. Williams the diagnosis in the first instance was made both by clinical and laboratory methods; treatment by arsphenamin and mercury was carried out, and all the symptoms, clinical and serological, disappeared. Two years later exposure was followed by the development of a sore in which spirochætes were demonstrated. It is true that a tertiary lesion may exactly simulate the appearance of a chancre; it may coexist with a persistently negative Wassermann reaction, it may be contagious, although the demonstration of spirochætes is rarely possible, and it may be accompanied by a satellite adenopathy. But, as Dr. Williams remarks, all these unusual phenomena rarely occur in the same person at the same time, and such cases may with greater probability be regarded as examples of reinfection in patients who have been cured.

THE R.A.M.C. ROLL OF HONOUR.

THE Official Roll of the officers of the R.A.M.C. who laid down their lives in the Great War is now published. The total number of names given is 709, divided as follows:—

Old and New Armies.		*Territorial Force.*	
Major-Generals ...	1	Colonels	2
Colonels	8	Lieutenant-Colonels	13
Lieutenant-Colonels	17	Majors	16
Majors	25	Captains	77
Captains	360	Lieutenants	5
Lieutenants	185		
	596		113

The Officers' Roll, comprising over 40,000 names in all, may be purchased from His Majesty's Stationery Office through any bookseller. It would be invidious to select any of the well-known names for particular mention; all these men deserve our perpetual honour and gratitude.

ANTITUBERCULOUS VACCINATION.

WE have previously drawn attention[1] to the antituberculous vaccine prepared in Italy by Professor Martinotti, of the University of Bologna. Some new evidence came to hand in *Annali di Medicina Navale*, the organ of the Italian Naval Medical Department, at the end of last year. The Director-General, Lieutenant-General F. Rho, was so much interested in this vaccine that he gave orders it should be examined in the Naval Hospital at Spezia, and the report by Professor Medical Lieutenant-Colonel (Surgeon-Commander) Dr. L. Sestini is now published. Professor Sestini discusses the 23 cases that were treated at Spezia in 1918-19 by Martinotti's vaccine, of whom 3 were cured, 9 were improved, 4 had no benefit (3 of these died), 1 patient was found unsuitable, and 6 withdrew themselves from treatment. The evidences of cure were disappearance of fever and tubercle bacilli, as well, gain in weight. Twenty-five further cases of also treated by this vaccine, but at Modena, are tioned, of whom, all ambulant cases, 17 were and so remained during the two years following, 3 showed no effect, and 5 proved unsuitable. These results are distinctly encouraging, but it is to be regretted that in this, as in other investigations of new treatments for consumption, no endeavour is made to report on other cases treated at the same time, but by the more usual methods, as controls for comparison. The recovery of tuberculous patients seems to depend so much on climate, food, and the clinical acumen of the physician that, consequently, a table of recoveries of patients under a special specified treatment may really be due to the greater skill of their physician. If, however, the cases of consumption entering a hospital, or some particular physician's clinic in that hospital, are numbered consecutively, and the even numbers, for example, are all treated with this remedy, while the others receive the treatment hitherto current, all being under the care of the same physician, marked improvement in the results observed could be ascribed with some confidence to the specific treatment. The profession would become instantly curious, and would at once give trial to the method.

---

[1] THE LANCET, 1920, ii., 563 and 1105.

MEDICINE, INDUSTRY, AND RESEARCH.

THE industrial welfare movement is one of the few good things which during the war received the impetus necessary for expansion, and which has survived. Previously in this country there had been small beginnings made by a few far-seeing and enlightened employers. The Ministry of Munitions seized upon these beginnings as a base from which to commence large-scale operations; but their activities ceased with the armistice. Since then the Home Office through Welfare orders made under Sec. 7 of the Police, Factories, &c. (Miscellaneous) Act, 1916, have consolidated much of the ground won. But without doubt the life of the movement to-day lies outside official circles. An instance of this was given by the Conference held at the Mansion House by the Industrial Welfare Society which was addressed by its president, the Duke of York. This society, which is keen and active and supported by the majority of male welfare workers, approaches the subject from the social and psychological side; its point of view is expressed every month in the *Journal of Industrial Welfare*, a publication the progress of which we have been watching with interest. During the past six months this journal has greatly improved, and it may not have been mere coincidence that the improvement followed hard upon certain friendly criticisms which appeared in these columns. Practical articles dealing with such subjects as industrial fatigue, psychology, and ventilation have appeared; a key to current literature is given; and informing reviews are published. Nevertheless, we still look in vain for any record of research undertaken by welfare workers. Another instance of welfare activity is the Welfare Workers' Institute, which receives the support of women welfare workers, and also publishes a useful journal—*Welfare Work*. But here, too, the social side of the work predominates, and little attention is paid to research as the foundation of welfare as a science. The tendency to look upon welfare as an art or mystery is pronounced, and equally pronounced is the absence of any clear recognition of the importance of health in welfare.

The welfare movement as a whole must gain further power from Sec. 20 of the Mining Industry Act, 1920. Under this section a fund is gathered from a levy of one penny per ton of coal raised, which must be applied for purposes connected with the social well-being, recreation, and conditions of living of workers in or about coal-mines, and with mining education and research. A small expert committee has recently been appointed by the Secretary for Mines to allocate the fund. Research is definitely included in the subjects upon which this fund may be expended, and one member of the committee is a medical man. We may hope that the mining industry the welfare movement will rt with a scientific and medical bias. No one who tches the development of the industrial welfare vement can fail to be struck with the rapidity th which it is spreading and with the small part which the medical profession is taking in it. Yet the movement is aimed at obtaining for the worker a healthy mind in a healthy body. So far as can be judged the tendency in America is in the opposite direction. Workshop after workshop continues to appoint whole-time doctors, who select healthy workers by preliminary examinations, and keep them in health when obtained. These factory medical officers initiate in every direction welfare activities based on knowledge of what is required. In this country we have a band of medical men, certifying factory surgeons, brought intimately into touch with industry, and we naturally look to them for light and leading. The annual report of their association for 1920 is before us; it contains no word of a forward constructive policy. To judge from the report this association is mainly concerned with the inadequacy of fees allowed for carrying out the few duties entrusted to them. No reference is made to the important part which industrial medicine should be taking in the life of the community.

The world is moving fast, and under our eyes a new science, the science of health in industry, is emerging. The publications of the Industrial Fatigue Research Board have been disclosing principles underlying human activity and indicating how health may be maintained. The hasty decision to extinguish the excellent work of this Board on the plea of so-called economy has been reconsidered. Wiser counsels have prevailed. In the past the maintenance of health has never had a practical economic interest for any definite group of persons; now in industrial employment it has. For there is to-day no more paying proposition than to engage a factory medical officer who knows his work. America has been quick to make the discovery and to seize the opportunity. Unless we follow we shall fall behind in industrial competition—and in national health.

A WATER-BORNE TYPHOID FEVER EPIDEMIC.

WATER-BORNE epidemics of typhoid fever on a large scale are, fortunately, not now so frequent in this country as they were some years ago. The efforts made by local sanitary authorities to protect their water-supplies from contamination have proved eminently successful. Typical water-borne epidemics of typhoid fever are often preceded by a period of heavy rainfall or a rapid thaw, by which surface and other impurities are carried, sometimes considerable distances, to water-supplies, this mode of pollution being of a sort that in ordinary circumstances would not have been anticipated in many instances. Often the first indication that such an epidemic is impending is the occurrence of a sudden and widespread prevalence of diarrhœa of varying severity, affecting a large proportion of the population; the outbreak of typhoid fever follows in about three or four weeks' time, corresponding to the incubation period of the disease, with an added week or so to give the medical practitioner time to arrive at a diagnosis before notification. Although such water-borne epidemics, as has been said, are now of comparatively rare occurrence with us, they are not uncommon in the United States. An interesting and typical instance on a somewhat extensive scale occurred towards the end of 1920 at Salem, an industrial town of about 10,000 inhabitants in the State of Ohio (not to be confused with the famous old Massachusetts city), a report on which was published in the *Journal of the American Medical Association* for Nov. 27th last. The water-supply of this town is derived from several groups of deep wells, from which the water is pumped to conduits which convey it by gravitation to a covered service reservoir. Repeated analyses showed the supply to be pure and of good quality. There are still some 400 privies in use in and on the outskirts of Salem. For some years typhoid fever had been practically absent from the town, and not a single case had been reported in the 12 months ended August, 1920. Towards the end of that month and beginning of September, however, three cases came under observation. Very heavy and prolonged rainfall took place at the end of September and beginning of October, immediately after which a widespread prevalence of "enteritis" occurred, affecting, it is said, more than half of the whole population of Salem. Some three weeks later cases of typhoid fever began to be notified in rapidly increasing numbers until Nov. 1st, when the height of the epidemic was reached. On that day 54 fresh cases were reported, the total attacks up to Nov. 20th amounting to 785, or nearly 9 per cent. of the inhabitants. After this the epidemic rapidly declined. The type of the disease was not severe, for only 12 deaths were recorded up to Nov. 20th. It was expected, however, that other fatal cases would occur, for on the last-mentioned date there were many persons still in the acute stages of the disease. The sudden and widespread occurrence of "enteritis" in the town during the early part of October cast suspicion on the water-supply as the source of the trouble. Bacteriological investigations showed that one of the conduits from a group of wells was conveying contaminated water to the service reservoir; it was therefore at once cut off from the public supply, and an emergency chlorinating outfit was installed, warning notices at the same time being issued to householders to boil all water used for domestic purposes. No doubt these measures helped to control the spread of the infection, but before they came into action the polluted water had already been drunk by many persons who afterwards developed the disease. The precise manner in which the water became polluted has not yet been stated, as at the time the report was published the investigations had not been completed. Among the other measures employed by the local health authority to control the spread of the disease was the offer of antityphoid inoculation, and this was accepted by about a fourth of the inhabitants of the town. Four emergency hospitals were established for the reception of the fever patients. The sewage of Salem is treated on intermittent sand filters, from which the effluent is discharged into the Beaver Creek, a tributary of the Ohio River. As soon as it was apparent that typhoid fever was becoming epidemic this effluent was chlorinated, with the object of protecting from infection the communities using the river water below Salem. One of the lessons to be learned from this epidemic is the necessity for constant and vigilant supervision of all sources of water-supply, no matter how pure these originally may have been.

"SACRALISATION."

A NEW word has been recently coined by French orthopædists to describe a condition which has long been known to the anatomist but has been strangely neglected by the surgeon. By "sacralisation" is understood the overlapping to a greater or less degree of the wing of the sacrum by the overgrown lateral process of the fifth lumbar vertebra. Ledouble, indeed, describes six varieties, the first two consisting of enlargement of the lateral process with overlap. The various papers contributed on this subject are ably summarised by Professor P. Mauclaire in the *Paris Médical*,[1] who points out that as a rule the condition gives rise to no pain. Curiously enough, when pain is present it appears, as a general rule, after the complete development of the pelvis during the third decade of life. Various hypotheses have been put forward to account for the pain, the favourite explanation being pressure on the lumbo-sacral nerve or on the nerves of the cauda equina. As for the cause of hypertrophy of the lateral process, this also remains undetermined, though an attractive theory has recently been put forward by Dr. E. Landoux and G. Caillods.[2] These investigators suggest that the transverse process of the last lumbar vertebra assumes the osteogenetic function of a sacral vertebrum. The practical conclusion would appear to be that in every case of backache of uncertain or unknown origin the lumbar region of the spine should be investigated under X rays. Resection of the enlarged process alone offers a satisfactory cure.

FEES FOR LIFE ASSURANCE WORK.

FROM time to time protests reach us in regard to the remuneration offered by life assurance companies to their medical referees. We have just received the specific complaint that to be paid half a guinea for a £100 policy or less and a guinea for policies of more than this amount is illogical and unfair, because the work involved is the same in both cases. The annoyance is natural, for no professional man likes to be asked to give his best work for an insufficient fee, or to be obliged to offer less than his best because the fee is inadequate. But there is something to be said on the other side. The companies state that reports they receive from their medical referees are often perfunctory, whatever the amount of fee paid, while they may lack data necessary for a just assessment of the risk or contain statements that are contradictory and mutually destructive. Some actuaries go so far as to assert that the protection afforded by medical examination lasts only for the first three years, and that, apart from these three years, a medical report might be dispensed with altogether; and it is admitted that were it not for adverse selection no medical examination of any kind would be necessary at all, for the risks could be worked out accurately from life tables on an actuarial basis. For this and other reasons many companies are extending largely their non-medical tables with apparently satisfactory results, and there is a real danger of this procedure increasing. We say "danger" advisedly, because we feel that non-medical insurance, while dealing a severe blow at medical prestige, would not be in the best interests of the community. No doubt in the past the fees offered may have been quite inadequate, and it was a public duty to resist them. Now when it is a question of standardising the examination fee at a higher level certain facts must be borne in mind. The premiums paid in the smaller insurances allow no margin for heavy medical expenses, and a disparity, though illogical, may be unavoidable. In ordinary practice the squire's daughter and the gardener's wife may demand equal care and attention, and yet the fee cannot be the same for each. The demand for larger fees would command a greater prospect of success in the case of policies for large amounts. Again, it must be remembered that individual prognosis remains fallible whatever the skill and care devoted to the examination, and no one knows this better than those responsible for the management of life assurance companies. Referees may rightly claim that the remuneration for work done should reward them fairly for their time and trouble; they should also have a care to convince business men that medical reports are essential to the economic working of life assurance schemes.

VENTILATION OF THE HOUSE OF COMMONS.

WE do not know the exact date of the first complaint concerning the ventilation of the debating chamber and other parts of the House of Commons—the House of Lords has apparently never required similar attention—but the subject probably came up within a very few years of 1852, when the legislature took possession of its present quarters. From time to time questions have been asked, select committees appointed, reports presented, and alterations undertaken—as, for example, the substitution of fans for exhaust furnaces—but close proximity to the river and the structure of the building itself seem to have been the main obstacles to any great improvement. In 1893, for instance, we noted in our columns that in spite of "electric light and purified air" Members of the House still suffered from "lassitude." It had already been pointed out that the floor matting which covered the air inlets, or lay near them, was a source of atmospheric pollution; during 1905 Dr. Mervyn H. Gordon issued a full report in which the air of the debating chamber was shown to be too dry, and, together with the air below the inlets, demonstrably contaminated by the matting. It was hoped that the gradual disappearance of horse traffic from the London streets would improve the bacteriological condition of the air. In 1906 it was made evident from a further report by Dr. Gordon that little was to be said against the quality of the air-supply, but Members still found it lacking in freshness. A vacuum cleaner was intoduced at about this time, and half a hundredweight of dirt thereby removed from the floor and precincts of the House each week. During the influenza epidemic of 1908 it was suggested that the disease was endemic in the debating chamber; active debate doubtless favoured the dissemination of infected air-borne material which was not efficiently removed by ventilation. In the same year a question was asked which drew in reply the statement that the admission of air otherwise than by the floor could only be effected by radical reconstruction of the chamber. Dr. Leonard Hill, who made a thorough investigation of the subject for the Select Committee appointed shortly before the war, recommended introduction of air at the top of the back of the benches and at the face of the gallery, with closure of the floor perforations; the Committee agreed to an experimental trial at a cost not to exceed £2000, and although the matter was set aside during the war a model is now under construction at the National Physical Laboratory in order that the Office of Works may test the movement of the air-currents according to Dr. Hill's plan. Sir A. Mond, First Commissioner of Works, was recently questioned concerning the proposed test, and stated in his reply that the result would be of general scientific value.

[2] La Presse Médicale, Feb. 12th, 1921, p. 123.

In the light of fresh complaints the ventilation of the debating chamber and its precincts still leaves something to be desired; until the temperature and humidity are properly controlled, and perhaps so long as reliance is made on quantity and velocity of air-supply alone, it will remain unsatisfactory. It is, however, doubtful if any means can be found of providing air, at once uncongenial to pathogenic organisms and altogether suited to human comfort, to a considerable number of people gathered in a large chamber.

THE SPAHLINGER SERUM.

OUR Swiss correspondent writes on March 6th: The sensational news in your daily press regarding the effects of the Spahlinger treatment in tuberculosis has occasioned some mild surprise in this country. Here the treatment is practically unknown, nor do we find its author on the list of registered medical practitioners in Geneva. So far as I have been able to ascertain, the serum has not been extensively tested in any of our Alpine sanatoriums. One wonders therefore at its fame abroad. Dr. Hector Cristiani, professor of bacteriology at, and director of, the Service d'Hygiène at Geneva University, asked by a representative of the *Journal de Genève*, stated that he had only heard of the new treatment through the daily press, Mr. Spahlinger never having made any communication to either of the learned societies of Geneva or elsewhere in Switzerland. His former communication to the Académie de Médecine and his recent communication to the Académie des Sciences, both in Paris, contained the clinical histories of certain patients under the observation of British physicians, and treated with his remedy, but they gave no indication of the method of preparation of the remedy nor of the nature of the substances injected. In such circumstances Dr. Cristiani felt it impossible to form any opinion of its value. Swiss law does not put any control on the manufacture of curative serums. Mr. Spahlinger, therefore, did not require any official authorisation to make his experiments. The Department of Public Hygiene of Geneva has had no occasion to intervene, as the preparation is not on sale in that city. Dr. Cristiani concluded by saying that it would only be possible to know something of its action when the composition and method of preparation of the Spahlinger serum were revealed. Control experiments over a period of years would then be needed. In the case of other serums their authors had lost no time before publishing details; it was then possible for others to repeat the experiments and to confirm their value. It was open to Mr. Spahlinger to do likewise.

THE COLLECTIVE VOICE OF MEDICINE.

THE old diplomacy had this to be said for it: its deliberations being held in secret it was easy for its pronouncements to be authoritative, the smooth phrases giving no hint of the struggles and compromises of which they were the net result. Doubtless medicine could speak with such an agreed though falsetto voice if its representatives felt it worth while. But no one supposes that the process would throw much light on the broad principles of health administration, which is what the public is desirous of learning from the professors of medicine. Open discussion has its own drawbacks in that the diversities may lead the unthinking to conclude that there is no underlying unity. Even the credentials of a would-be spokesman may be called in question. We dealt a fortnight ago with some aspects of this evergreen problem, and return to it to state that no organisation which has accepted membership in the Federation of Medical and Allied Societies has subsequently withdrawn from federation. The Royal Society of Medicine, the British Dental Association, the Medico-Psychological Association, the Chartered Society of Massage, the Pharmaceutical Society, amongst others, are, we learn, all glad to use this Federation for expressing a collective opinion on matters which concern them in common. The British Association of Radiology and Physiotherapy has recently applied to be federated. The Federation seems likely to make good its claim to guide public opinion without interference in the internal affairs of its constituents. Those who prefer substance to formality can hardly fail to wish it well.

THE PROMOTION OF INTERNATIONAL MEDICAL INTERCOURSE.

Dr. G. Monod's efforts to bring about closer coöperation between representative bodies of French and British medical men have not been fruitless. At a recent meeting of the Executive Committee of the Fellowship of Medicine and Post-Graduate Medical Association three different aspects of the question were considered, and the resolutions passed should at any rate clear the ground for the discussion of more definite proposals in the future. It was resolved, as a preliminary step, that the Information Bureau of the Fellowship of Medicine should be brought into closer communication with the Bureau of the Association pour le Développement des Relations Médicales (A.D.R.M.), in order that those desiring to take post-graduate courses in either country should more easily acquire detailed information as to their scope. The Committee next recorded its approval of the principle of reciprocal visits of lecturers on special subjects and its readiness to give assistance in the promotion of such occasional lectures. Lastly, the A.D.R.M. were invited to make suggestions as to how the exchange of medical literature could best be encouraged, and these we await with interest. The coöperation of great teachers should increase if such visits as that now being paid to Paris by Scottish students become more general. The 35 undergraduates of the University of Edinburgh who are at present taking a course of practical midwifery under the direction of members of the Faculty of Medicine of Paris will certainly want to keep in touch with their French teachers. It is at an early stage in medicine as in life that friendships and alliances are most easily formed, and a series of organised study excursions, as part of the curriculum of universities on both sides of the Channel, would probably do much to promote the desire for intercourse in later medical life.

THE death, at the age of 77, of John Fletcher Moulton deprives the world not only of a brilliant mathematician and scientist, but of a man of wide interests and varied achievements. Senior Wrangler and First Smith's Prizeman in 1868, a Fellow of the Royal Society in 1880, Queen's Counsel and Member of Parliament in 1885, an Appeal judge and Privy Councillor in 1906, Life Peer as Lord Moulton of Bank in 1912, he was the first chairman of the Medical Research Council and during the war Director-General of the High Explosives Committee.

THE LANGHAM TELEPHONE EXCHANGE:

MEDICAL MEN'S NEW NUMBERS.

THE new Langham Exchange, situated at the Western District Post Office, Wimpole-street, London, W. 1, was opened at 2 P.M. on March 5th, when the circuits of a large number of medical men and dentists practising in the Harley-street area were transferred from the Mayfair Exchange. Since the new numbers cannot appear for some weeks in the Telephone Directory we are giving a list, so far as can be traced, of the doctors and dentists on the new exchange with their new numbers. The direction of the London Telephone Service is in the meantime doing what can be done to mitigate inconvenience. All callers asking for the old Mayfair numbers will be connected to a special inquiry officer at the Mayfair Exchange, provided with a card index, who will advise the caller of the new number. The calling subscriber's telephonist will also *be advised of the change and instructed to complete* the connexion to the new Langham number.

CONTROL OF VENEREAL DISEASE.

Venereal Disease Clinics.

WHEN the atmosphere of discussion enveloping the expediency or possibility of prophylaxis of venereal diseases becomes close and sultry, it is well to remember the development of widely spread and well-organised efforts towards the reduction of these diseases. If we consider that in this country until a few years ago not a single authorised centre was in existence, it becomes obvious that much has already been achieved in a comparatively short period. The difficulties encountered were many and in some instances formidable, and the way they have been surmounted in the past gives hope that, if only all parties will work together, enormous strides will be made in the eradication of venereal diseases in the future. From a study of the list of treatment centres approved by the Ministry of Health under Article III. of the Public Health (Venereal Diseases) Regulations, 1916, we note that there are now in existence 176 recognised centres, at nearly all of which treatment is administered to both men and women. Taking into regard the difficulties which still exist, criticism would be out of place, but we offer certain suggestions in a spirit of hopeful commentary. We note that in 31 clinics there are no evening sessions for men. This is a serious omission, since the industrial classes are usually prevented by economic reasons from attending during the earlier part of the day. It is true that in certain instances clinics are open on Saturday afternoons, but this does not satisfy the need. Every clinic should be open at least three times a week, and at hours when the majority of patients can reasonably expect to attend. Moreover, the provision of irrigation treatment between the actual sessions of the clinics is most important; there are still very many clinics at which this convenience is not afforded. We may hope that the next year will see a great improvement in this respect, as well as increased opportunities for female patients to obtain this valuable adjuvant treatment.

Marriage of Syphilitic Women.

We have already commented[1] on a recent discussion at a special meeting of the Société Française de Dermatologie et de Syphiligraphie on the marriage of syphilitic women. As a preliminary the following two recommendations were made: (1) Unification of methods of treatment; (2) unification and standardisation of technique in the performance of the Bordet-Wassermann reaction. Dr. Louis Bory, in a communication to the *Progrès Médical* of Jan. 15th, divides cases for consideration into two groups: First, those who present themselves for treatment in the early primary stage before the appearance of a positive blood reaction; and second, those who start treatment subsequent to the development of a positive W.R. As a suitable course of treatment for the first-named group he advocates the following: A preliminary course of an arsphenamine preparation with a total dosage of 3·5 g. for medicaments of the 606 type, and of 4·5 g. for those of the 914 type, the course lasting two months—a month's rest—and a W.R.; a second course "de sécurité" identical with the previous course lasting two months, another month's rest, and a W.R. Following this an additional treatment with mercury lasting six months. Mercury is given in weekly injections of grey oil or of calomel in courses of two months with a month's interval between them. At the end of this mercurial treatment a lumbar puncture and examination of cerebro-spinal fluid are performed. The year of treatment having terminated, a year of observation is carried out with periodic examinations of the blood, and a second lumbar puncture. If all these examinations prove negative the patient is allowed to marry at the end of this second year. For those who have not come under treatment until a positive W.R. has developed a second year's course is prescribed. If at the end of these two years the blood reactions and examinations of the cerebro-spinal fluid prove negative a two years' period of observation is recommended. During this time regular examinations are performed and a provocative W.R. done at the end of each year. A lumbar puncture terminates the period of observation. If this is negative marriage is permitted. In the opinion of Dr. Bory the same tests should be used for the male as for the female.

Return of the Far East Commission.

The Commission appointed by the National Council for Combating Venereal Diseases and sent out to the Far Eastern ports under the ægis of the Colonial Office has completed its itinerary, and will arrive in England on March 14th.

Conference of Public Health Authorities.

A conference of public health authorities took place at 5, Cadogan-gardens, London, on March 1st, Lord Askwith presiding, to consider the prevention of venereal disease. Dr. A. Mearns Fraser proposed:—

> That, in view of the terrible effects of venereal diseases on the health of the nation, and especially because of their effects upon women and children, there is urgent need for health authorities to institute active measures to protect the inhabitants of their districts against these diseases. Of these measures by far the most important is education of the public as to the dangers of venereal diseases, as to the manner in which they are spread, and above all, education in the methods of immediate self-disinfection, by which venereal diseases can be largely prevented.

Dr. Fraser said that the Society for the Prevention of Venereal Disease was anxious to induce local authorities to make known the methods of self-disinfection to the public, and he detailed the action already taken in this direction by the Portsmouth Health Committee. Dr. Charles Saunders, in seconding the resolution, said that among the 300,000 inhabitants of West Ham there were more than 1000 new known cases of venereal disease every year.

Dr. E. W. Hope, Dr. W. A. Bond, Dr. J. Holroyde, and other medical officers of health and prominent municipal officers supported the resolution, which was then put to the meeting and carried unanimously with the following addendum:—

> Resolved further that this resolution and opinion be forwarded to health authorities throughout the United Kingdom, with the request that they take the subject at once into consideration.

Sociological Teaching to Medical Students.

On Tuesday, March 1st, the first of a course of lectures on gonorrhœa was delivered at the London Hospital by Mr. Hugh Lett, director of the Gonorrhœal Clinic, who gave an admirable résumé of the subject of venereal disease as viewed from the sociological standpoint. He pointed out how necessary it is for medical practitioners to evince such an interest as will enable them to reply with authority and confidence to the inquiries to which, as medical men, they will certainly be subjected. Further, he showed how important it is that medical men should possess such a knowledge, in order that they may be able not only to offer information and guidance but also at times to restrain well-meaning but ill-considered attempts to reduce venereal disease. Mr. Lett drew a comparison between the prurient and false modesty adopted in the mid-Victorian era and the more wholesome candour which marks the present day, epitomising the activities of the Royal Commission on Venereal Diseases, the National Council for Combating Venereal Diseases, and the Society for the Prevention of Venereal Disease. He explained and dealt in a judicial manner with the controversy concerning immediate self-disinfection and early preventive treatment, ending with a consideration of the difficult subject of notification. Such a lecture, we believe, is something of a novelty in a teaching school, and the example of the London Hospital might well be followed in bringing before medical students and practitioners the necessity for developing a sociological interest in these diseases. If once the sympathy and coöperation of the medical profession as a whole were enlisted it would be a far easier task to influence popular opinion.

---

[1] THE LANCET, Feb. 26th, p. 447.

LUNACY IN EGYPT.

THE Twenty-fifth Annual Report on the Government Hospital for the Insane at Abbasayi and the Eighth Annual Report on the Asylum at Khanka are, as usual, full of interest, and give evidence of the steady progress which has been made in Egypt in the treatment of the insane, notwithstanding the very trying experiences of the last few years. The period covered by the reports coincides with the financial year 1919–20. The number of beds on the establishment is 1581—i.e., 1181 at Abbasayi, 400 at Khanka. The admissions, exclusive of transfers between the asylums, reached a total of 919. Besides cases admitted to the two asylums, many patients were admitted to the local hospitals of the Department of Public Health. We must once again point out the importance of having other asylums scattered about in different parts of Egypt.

The total number of cases of insanity brought under official cognisance during the year is found to be 1098, which, compared with the 1281 in 1918, shows some diminution. 635 cases were discharged, of whom 175 had recovered, and 26 were found not to be insane; 430 cases were handed over to their relatives—while still insane—in most instances because accommodation was needed for new and more acute cases. The reduction of 159 in the admissions did not result in any relief of the pressure for room, owing to a reduction of 200 in the number of beds. The old troubles have arisen from want of accommodation, there being on the one hand a considerable amount of crowding, and on the other the necessity to discharge many patients who are only, apparently, convalescent. Discharge of convalescent patients to their old and in many cases unhealthy surroundings has as usual led to the patients being later returned under the head of criminals. Again, it has to be noticed that there is no real criminal asylum, and that the majority of the people who are reported to be criminally insane are sent to Abbasayi.

Diet and Mental Disease.

The death-rate among the insane patients has diminished from 21 per cent. in 1918 to 11·9 per cent. in 1919; calculated on the total treated, it has dropped from 13·4 per cent. to 8·2 per cent. The reduction in the deaths affected nearly all causes given in Table 10, except general paralysis. The greatest reductions were as follows:—

Pellagra … … … … … … … … … … … …	66
Dysentery and diarrhœa … … … … … … …	25
Exhaustion from brain disease and epilepsy … …	28
Lung and heart disease and tuberculosis … … …	33
Influenza … … … … … … … … … … …	30

The great reduction in the deaths from pellagra and from other diseases is evidently due to some common cause, and this cause seems to be the improvement in the diet proposed in last year's report, and put into force on May 1st, 1919—namely, an increase of 45 g. of meat and 50 g. of milk daily in the diet of each patient. The importance of this fact is manifest, in view of the doubt recently thrown upon the relationship existing between pellagra and diet, certain investigations having pointed to infection and dysenteric troubles as ætiological factors. But the observations of Dr. J. Warnock and Dr. H. W. Dudgeon confirm the impression that pellagra is chiefly associated with defective diet. These should be read in connexion with the special report on pellagra among the Turkish prisoners of war, published by the British War Office, in which the conclusion was reached that lack of sufficient biological value of protein stands in ætiological relationship to pellagra, certainly as an exciting factor, and possibly as a determining factor, while the low biological value of the protein of maize was suggested as the reason for the frequency of pellagra among maize consumers.

The Causes of Insanity.

As usual, pellagra appears as the chief cause of mental disorder in Egypt—or, at all events, as being an associated cause in the production of insanity—and when the different groups are analysed it is found to be equally represented in each. Thus, of the forms of insanity of 52 male and 5 female accused persons—i.e., those accused of crimes—10 of the 52 owed their insanity to pellagra. Table 5 gives the forms of insanity admitted, and there again it is noteworthy that hashish and alcohol play an important part, although that part is small in comparison with pellagra. Epileptic insanity is also frequent. General paralysis of the insane occurred in a considerable number of patients, and, as we have pointed out before, a very large number of female patients—in fact, a much larger proportion of female to male patients—is met with in Egypt than in England. As usual, the large proportion of general paralytics is furnished by the cities, such as Cairo and Alexandria; whereas pellagra occurs more commonly in the country districts. Cairo provides most of the cases of insanity due to hashish. Table 9 attempts to give the causes of insanity, and suggests the relationship of heredity to the production of mental disorder; difficult as it is in England to obtain any trustworthy history where heredity is concerned, that difficulty is greatly increased in Egypt among illiterates. Syphilis is given as a very definite cause, occurring both in men and women, not only producing general paralysis, but also other forms of disorder.

A striking fact as seen from the tables is the length of residence in hospital of patients who recovered, a considerable number being discharged who had been in asylums for seven years and upwards. Seclusion had to be resorted to in a fair number of cases, depending to a great extent upon the crowded condition of the asylum. No mechanical restraint was employed during the year, and hypnotics were used to a limited extent. Five patients sustained fractures from falls or struggles with other patients; one patient sustained a fracture of the humerus, another a fracture of the clavicle. None of the fractures was fatal. Post-mortem examinations were made in only 16 instances. The staff, both English and Egyptian medical officers, has been increased, and has been maintained in its efficiency.

The Khanka Report.

Turning to Dr. Dudgeon's report at Khanka, it appears that for some considerable part of the year he was taking the place of Dr. Warnock, who was in Europe. Dr. Dudgeon provides interesting tables, showing the rate of admissions, the percentage of pellagra admissions, and the death totals; graphic schemes are given showing these facts in relationship to the Khanka institution. Steady progress is recorded in regard to the farms and the supply of water, and the planting of trees is being carried on satisfactorily. At Khanka are received the more quiet patients, and no women—a rather special class, from whom more work can reasonably be expected than from patients elsewhere. Careful examination was made of stools in reference to dysentery and diarrhœa. The results bear out the findings in last year's report as regards the presence of intestinal worms. Dr. Dudgeon has succeeded, during the past year, in maintaining the standard of no seclusion or restraint; he has also been able to reduce the administration of sedatives to a very satisfactory point.

The reports, considered together, make clear the facts that lunacy in Egypt is being satisfactorily treated, and that, with time, the further development of lunacy legislation, and the establishment of local asylums, with the separation of criminal lunatics, will have a very beneficial effect. The reports themselves are models of care and accuracy, both from the medical and the economical point of view.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

District Medical Officers for Scotland.

THE Scottish Board of Health announce the appointment of the following district medical officers:—Senior district medical officers: Western District (headquarters, Glasgow), Dr. R. Buchanan; South Eastern District (headquarters, Edinburgh), Dr. A. M. McIntosh, C.M.G. Junior district medical officers: South Western District (headquarters, Glasgow), Dr. John Gilmour; Northern District (headquarters, Aberdeen), Dr. John Jeffrey; Eastern District (headquarters, Dundee), Dr. J. Murray Young. These officers will act as medical referees in cases referred to them on questions of incapacity of insured persons for work, and as consultants in questions of diagnosis and treatment. They also have important administrative duties in connexion with the Insurance Medical Service and other work of the Scottish Board of Health.

Annual Dinner of the Royal Medical Society, Edinburgh.

This, the first post-bellum revival of an important Edinburgh medical function, was held on Feb. 22nd, in the hall of the Royal College of Surgeons of Edinburgh, by the kind courtesy of the Council. The chair was occupied by Dr. J. Davidson, senior president of the society, who welcomed the guests. The guest of the evening was Professor Robert Muir, M.D., F.R.C.P., F.R.S., of Glasgow University. After the loyal toasts had been drunk, the Lord Provost of Edinburgh proposed the toast of "The Imperial Forces"; Admiral Sir Herbert Heath replied for the Navy, and Lieutenant-General Sir Francis Davies for the Army. The chairman, in proposing the toast of "The Guest," said that Professor Muir was an old member of the society. Twenty years ago he went to Glasgow, where he gathered round him a body of workers, and gave to Glasgow her reputation as a school of pathological research. Professor Muir, in reply, said that such gatherings tended to a spirit of generosity and exaggeration; they had honoured him beyond his merits, and ever afterwards when he looked back there would be nothing he would prize more highly than the night on which he had been the guest of the Royal Medical Society. In proposing "The Royal Medical Society," he said, he had the difficult task of making two speeches in the one evening. He referred to the early history of the society, to its formal institution in 1737, its activities, and the fact that at an early period the society came to regard itself as an essential part of the medical school. In spite of disputes and quarrels from time to time there was no doubt that the Medical Society had very great influence in the growth and development of enthusiasm for the good of the school, and in 1778 the society was incorporated by Royal Charter. Professor Muir then referred to his own connexion with the society and wished all success to the younger generation in their conduct of its affairs. He ressed the wish that the spirit and the motive existed from the opening of the society might evail, and that honest inquiry, free criticism, and mutual help would always dominate in all that the society did. Dr. J. Lewis Owen, in reply, said that in common with other great bodies the society had passed through its times of adversity, but that it still continued to carry on the good work. Dr. J. M. Watt proposed the toast of "The University and Royal Colleges," and spoke of the great numbers of students who came to the Scottish schools of medicine from overseas. Principal Sir Alfred Ewing, replying for the University, said that the association of the University and the Royal Colleges was one of close and friendly partnership, and referred to the scheme for the commemoration of Lister and also to the scheme for raising funds for the University. Sir Robert Philip, replying for the Royal College of Physicians of Edinburgh, referred to the early foundation of the latter and to the close association between it and the Royal Medical Society. Dr. George MacKay, replying for the Royal College of Surgeons, Edinburgh, took the opportunity of expressing the pleasure which it gave his College to provide its hall for such a banquet. Dr. Freeland Fergus replied for the Royal Faculty of Physicians and Surgeons, Glasgow, and said that Edinburgh had once taken a good man from Glasgow in the person of William Cullen, but that Glasgow had now made up for this in its possession of Professor Muir. Dr. J. F. C. Haslam, in proposing the toast of the "Sister Professions," spoke of the high missions in this life which the Church, the law, and medicine, each in its own sphere, must keep before them. The Dean of the Thistle replied for the Church and the Solicitor-General for the law. Mr. Miles then proposed the toast of "The Chair," and the banquet concluded with "Floreat Res Medica."

University of Aberdeen War Memorial.

The University of Aberdeen is preparing a record of the services of its members during the war, and memorials to those of them who fell in action or went down with their ships, or died of wounds or disease. The record contains about 3000 names of graduates, alumni and members of the staffs, with particulars of the service of each, and of the distinctions gained. It is to be preceded by brief biographies with portraits of the 337 who laid down their lives for their country. A large part of the volume has gone to the press and the rest is rapidly nearing completion. The memorials which have been planned consist of a stained-glass window in the ante-chapel of the University Chapel at King's College with oak panels on the walls bearing the 337 names; of another window in the chancel; and of a memorial porch in Marischal College. The total cost of these memorials has been estimated at between £9000 and £10,000. Up to this time £4700 have been subscribed, but further subscriptions are necessary and may be sent to the principal or to the honorary treasurer, Mr. D. M. M. Milligan, 12, Dee-street, Aberdeen.

March 7th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Further Researches on Encephalitis Lethargica.

AT a recent meeting of the Société de Biologie MM. C. Levaditi and P. Harvier have given the results of further experiments carried out on animals, with special reference to the inoculation of encephalitis lethargica to rabbits. Some of their findings may have a direct application to the prophylaxis of encephalitis lethargica, since they have observed that the virus of the disease remains active for a long period in water and in milk.

Medical Aspects of Conscription.

The Minister of War in a letter to the members of the Académie de Médecine has set forth the following three questions: (1) At what age between the ages of 19 and 21 should conscription most suitably take place from a medical point of view? (2) What is the best season for men to join the colours? (3) Is resistance to fatigue and diseases diminished in men who have been rationed during the war? A committee was appointed to consider the three answers and Mr. Léon Bernard has recently submitted its report. The committee recommends the age of 21 as the most suitable for incorporation of men into the army, and has decided that the end of April is the best time of the year for calling them up. On the last point the conclusion reached was that the resistance of men who had been rationed during the war was diminished. In the course of the debate on the report Mr. H. Vincent gave statistics referring to contagious diseases (scarlet fever, measles, mumps, diphtheria, cerebro-spinal fever, typhoid fever, and paratyphoid) which occurred in the French army in recent years, showing that the morbidity was 5·78 per 1000 amongst men of 20 years of age and 5·25 per 1000 amongst men aged 21; these figures indicated that resistance was about the same in both groups. Other members were in favour of the age of 20 for the enrolment of conscripts providing the recruits were properly selected and properly cared for. The answer to the Minister dealt first with recommendations concerning the welfare of young recruits, more especially with regard to their training, clothing, feeding, and to hygienic conditions in barracks. The members of the Académie de Médecine finally declared that in their opinion men could join the army at 20 if these recommendations were carried out. The matter is of some importance; Mr. G. H. Lemoine points out in an article in the *Revue d'Hygiène* that in the event of mobilisation the contingent of the French army is increased by 200,000 men when the age of conscription is 20 instead of 21.

The Société de Neurologie.

Mr. Henry Meige, the general secretary of the Société de Neurologie, has announced at a recent meeting that the Réunion Neurologique Annuelle de la Société de Neurologie de Paris will be held in Paris on June 3rd and 4th. The subject for discussion will be the Syndrome of Parkinson's Disease, to be opened by Mr. A. Souques.

International Congress of Medical History.

An International Congress of Medical History will be held at the Faculté de Médecine de Paris from July 1st to 5th. Professor E. Jeanselme and Professor P. Ménétrier will preside over the Congress, which will consist of meetings, conferences, and visits to hospitals and museums. A museum of medical history will be inaugurated. The committee of the Congress invites any body in possession of historical medical curiosities (instruments, medals, engravings, pictures, sculptures, books, &c.) to lend such articles for a temporary retrospective exhibition. Further information can be obtained from Mr. Laignel Lavastine, Secrétaire-Général du IIe Congrès International d'Histoire de la Médecine, 12 bis, Place de Laborde, Paris (VIIIe).

Modification of the Internat Competition.

It has been finally decided to modify the form of the "Concours de l'Internat" on the lines indicated in my last letter. By order of Mr. Louis Mourier, Directeur de l'Assistance Publique, the modification will be applied to this year's competition.

March 5th.

ROUMANIA AND HUNGARY.

(FROM OUR OWN CORRESPONDENT.[1])

Cholera Prophylaxis in Bessarabia.

THE high degree of efficiency which characterises the work of the Medical Department of the Roumanian Army has been well illustrated in Bessarabia, where in the fiscal year of 1920 there was not a case of cholera among the Roumanian troops, although the disease was common amongst the natives and in the neighbouring Russian provinces. In numerous towns adjacent to military posts the disease was epidemic at some period during the year. The achievement of the Medical Department is said by the Surgeon-General in his annual report to be due to the thoroughness and effectiveness of the sanitary measures employed. The Roumanian soldiers have been thoroughly trained to abstain from eating uncooked native vegetables, and from drinking any but sterilised water. In the old Bessarabian (late Russian) soldiery there were only 9 cases with 7 deaths; these figures testify to the influence of the army system of sanitation, even with people accustomed for centuries to conditions of living that foster such diseases as cholera.

Hostels for University Students in Bucharest.

The question of hostels and residences for students has occupied the attention of the educational authorities in Bucharest for a considerable time. The existing conditions are anything but satisfactory. Students are frequently unable to get convenient apartments, and during the last two years the position has become more and more difficult. Even in the suburbs exorbitant rents are charged. Financial and other considerations have hindered the provision of hostel accommodation. The financial committee of the University wishes to establish a number of small hostels, each to accommodate some 50 students. This scheme would enable them to erect the hostels in different districts, possibly outside the city area, so that students might have the benefits of country residence with easy access to their training centres. So far, nothing definite has been done in the matter of securing sites beyond the inspection of certain pieces of ground, but the committee anticipates making an early start with whatever scheme may be decided upon. Meantime, several houses have been taken for temporary residences, and the committee hopes soon to be able to have accommodation for 200 students. These hostels will probably be opened in time for next session.

Epidemic of Sore-Throat in Kisenew.

An extensive epidemic of sore-throat has been prevalent in Kisenew, a large industrial and commercial centre in Bessarabia, during December, 1920, and January, 1921, and in many cases entire households have been attacked. The sore-throat was generally accompanied with painful and sometimes suppurative tonsillitis, and with enlargement of the glands of the neck. Attacks were often ushered in with rigor, and cases are recorded with a temperature of 39·8° C. The attacks were generally followed by marked depression and weakness lasting for several weeks. Streptococci and some staphylococci were found, but no diphtheria bacilli. The great majority of the cases occurred in outlying parts of the town inhabited by the poorer classes. Antistreptococcic serum did not seem to be of much use, and it was reported that in only one or two instances did vaccine made from the actual organisms appear to relieve symptoms. Only a few cases of acute rheumatism are known to have followed the attacks; the best results seem to have been given by aspirin, together with local antiseptics.

Pasteurisation and Grading of Milk in Budapest.

The department of health of the city council of Budapest at its meeting on Jan. 31st adopted resolutions which provide that all milk and cream offered for sale in the city, except that used for manufacturing or cooking purposes, must be of the grade technically recognised by the Board of Health as certified or guaranteed milk, or must be pasteurised under the conditions prescribed by the Board, following the system long employed in America. Grade A, for infants and children, is to be sold in bottles only. (This includes certified milk, guaranteed milk, or milk pasteurised under special regulations.) Grade B, milk safe for adults, to be sold in bottles or drawn from containers, not dipped. (This includes Grade A and pasteurised milk produced under the regulations of the [illegible]) Grade C, milk suitable for cooking and baking [illegible] to be sold from bottles or from cans. (This [illegible] milk complying with the [illegible] No one should use milk inferi[illegible] A [illegible] an infant or child. Every person purchasing milk for drinking purposes is entitled to receive milk not inferior to Grade B. The efforts of the department of health in the supervision of milk should be especially concentrated on Grades A and B.

Hence his familiarity both with Budapest and Bucharest which has misled some of our readers into thinking that we were imperfectly informed of the present geographical boundaries of Central Europe.—ED. L.

Traumatic Lesions of the Eye.

Dr. Mulgund, who during the war had under his care an eye hospital accommodating 600–800 eye cases, besides 1000 trachoma cases, has issued a little book on the above subject, comprising his war experiences. In this book he presents the general principles of treatment of trauma of the eye, remarking with regard to prognosis that all nervous disturbances in the orbit resulting from pressure of extravasated blood in the region are capable of complete retrogression, while direct lesions of the nerves usually persist unchanged. Special care must be taken to prevent drying or ulceration of the cornea when the eyeball protrudes or the lids do not close perfectly. If inflammation develops in the orbit from infection from the nose the prognosis is almost inevitably bad. Emphysema, on the other hand, has an excellent prognosis. Treatment of all fractures deep in the orbit should be exclusively conservative. With much suggillation a compressive bandage, ice-bag, and complete repose may be indicated. Only with extreme protrusion of the eyeball or very severe emphysema is it necessary to relieve by evacuation of the blood at the most swollen part of the orbital tissue. Direct operative measures are necessary if there is a fracture of the walls of the orbit with dislocation. Compound fractures should be treated on the usual surgical principles. Mulgund adds, in conclusion, that in every extensive compound fracture of the orbit, as also in every case of extensive injury of the soft parts in which contamination with soil cannot be absolutely excluded, a preventive injection of tetanus antitoxin should be given.

A Note on Antimalarial Operations in Albania.

The country of Albania is partly mountainous and partly a plain intersected by a network of rivers and streams, and abounding in pools, swamps, and forests. The latter is a paradise for mosquitoes. During the occupation of Albania by the Austro-Hungarian Army in 1916 the Surgeon-General deputed a native doctor, Dragomir Petrovic, to survey the country for the purpose of devising measures for the suppression of malaria. The suggested undertakings included improvement of drainage, destruction of the mosquito's breeding-places, and distribution of quinine during the fever season at an estimated cost of 3,500,000 kronen (quinine being at that time excessively dear). His report for the five years, 1916–20, published in January, 1921, indicates that these suggestions were put into active operation during this period. Drains were levelled and cleared or filled up, forests cut down, compounds cleared, pools abolished, tanks and watercourses systematically oiled by gangs of soldiers and ex-soldiers, and quinine lavishly distributed. This work appears to have been strenuously carried out at a cost of over 7,500,000 kronen. Dr. Petrovic considers that the statistics for 1920 show a slight diminution of malarial disease; but these statistics are not very reliable, and the present chief sanitary inspector of the district thinks that it is still too early to form any definite conclusions. Similar operations were carried out in Bosnia with still more doubtful results. Screening houses with wire gauze was tried there, but the inhabitants objected on account of interference with ventilation.

Feb. 18th.

SCOTTISH WOMEN'S HOSPITALS HONOURS.—The King has granted to the following medical members of the Scottish Women's Hospitals for Home and Foreign Service permission to wear decorations of the Order of St. Sava, conferred upon them by the King of the Serbs, Croats, and Slovenes in recognition of their services to the Serbian ick and wounded in the late war:—*Fourth Class:* Dr. trice A. McGregor. *Fifth Class:* Dr. Lilian M. Chesney, Janet McVea, Dr. Elizabeth Brook, Dr. Catherine L. bett, and Dr. Janet S. Laird.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

COUNTY OF BEDFORD.

Dr. H. Kenwood, in his annual report for the year 1919, explains that for the statement of birth- and death-rates respectively two somewhat different estimates of population are employed. The "death-rate population" excludes all non-civilian males, whether serving at home or abroad. This is necessary for the purposes of local death-rates, because it has proved impossible to transfer the deaths of non-civilians to their areas of residence, or to deal in any other satisfactory manner with the local mortality of this element in the population. These estimates are based mainly upon the rationing returns placed at the Registrar-General's disposal by the Ministry of Food. The "birth-rate population," on the other hand, is intended to include all the elements of the population contributing to the birth- and marriage-rates. It consists, therefore, of the "death-rate" for civilian population plus all non-civilians enlisted from this country, whether serving at home or abroad. This non-civilian element has been distributed over all the districts in the country in proportion to their estimated civilian population. The county birth-rate for the year under review was 15·9, as compared with a rate of 15·5 in 1918 and 16·0 in 1917. The general death-rate was 11·0. It is interesting to note that the death-rate for the rural districts exceeded that for the urban districts, a circumstance which doubtless is sufficiently explained by the considerable exodus from the rural districts of persons from 15 to 30 years of age, among whom the death-rate is exceptionally low.

Dr. Kenwood makes some interesting remarks on the recent *influenza* epidemic, which caused a civilian mortality throughout the country at the rate of 4774 per million per annum, an epidemic mortality not hitherto equalled in Britain since registration commenced. Nor does this heavy mortality truthfully represent the ravages of the disease; for the deaths attributed to pneumonia, bronchitis, heart disease, and phthisis were also markedly increased as the consequence of the influenza infection. Moreover, the age distribution of the attacks and of the deaths markedly departed from that of previous epidemics. From 15 to 35 were the years of highest mortality in the epidemic of 1918–19; whereas the most fatal years of previous epidemics were those of 55 and over. In Dr. Kenwood's view inoculation against the disease is of value in protecting against fatal complications rather than against attack of the disease. The Ministry of Health has made a vaccine available for distribution through medical officers of health to medical practitioners, and doubtless in the event of another epidemic this precautionary measure will be widely adopted. The epidemic showed the need of a promptly available supplementary personnel for temporary employment in time of public health emergency. Nurses are required in epidemics of influenza, measles, and whooping-cough who can visit all the poorer homes in which it can be ascertained that such disease has occurred, and it would be well if these services could be supplemented by a voluntary personnel suitably trained to offer good advice and to make inquiry with the view of ascertaining which cases are really necessitous. Our recent war experience has shown that there are in every community persons who would be able and willing to volunteer for such emergency services if they were invited to do so. Dr. Kenwood thinks that the suffering and mortality in an influenza epidemic could be materially reduced by adequate nursing assistance; a provision of fuel, food, and clothing to really necessitous cases; by hygienic advice, more particularly as to ventilation and the spacing out of the rest of the family; the distribution of a suitable disinfectant with directions as to its use; and the provision of more hospital isolation and treatment.

On the subject of the prevention and treatment of *tuberculosis* Dr. Kenwood remarks that the causes of the disease are largely economic, and the prevention is therefore largely in the hands of the social reformer. Better housing and the means to secure a more hygienic standard of living, the avoidance of excessive strain and too prolonged hours of work in badly ventilated premises, will all operate toward the reduction of the incidence of the disease by reducing the numbers of those with lowered resistance. But lowered resistance must be associated with exposure to infection if a person is to acquire tuberculosis, and it is in connexion with the advanced cases that these two factors assert themselves most prominently. The subject of advanced phthisis is very often an individual who has been for some time incapable of earning a living wage, and therefore he and those dependent on him are frequently on the border-line of poverty. He is giving off large numbers of germs in surroundings which favour their transference to others, and these others, who are exposed to such "massive infection," have had their resistance lowered by all the circumstances associated with poverty. As Dr. Kenwood has pointed out in previous reports, our national scheme for the treatment and prevention of tuberculosis provides no effective remedy for this state of things; and, indeed, the real remedy is both difficult and costly. It is to be found in powers for compulsory removal of those thus exposing others to grave risks, and in suitable provision for their isolation in hostels.

Tuberculosis schemes are deficient in another important respect. The average stay in the sanatorium provided for the poorer section of the community is about 12 weeks. This period is valuable in several respects, but it is doubtful whether anyone is ever cured in much less than 12 months of sanatorium treatment, which, of course, implies abundance of fresh air, abundance of good food and rest, carefully regulated exercise or work, and skilled medical supervision. A patient who is not in very comfortable financial circumstances cannot maintain those essentials after his discharge, and so he gradually loses what he has gained on the road to recovery, and he mostly dies from tuberculosis within two years from the date of his discharge from the sanatorium.

JUVENILE EMPLOYMENT AT CARDIFF.

Occupational legislation, first by adopting the principle that there should be a minimum age for employment, and later by raising this age from time to time until the present limit was reached, which in its turn, when the Education Act of 1914 is in full swing, will be further advanced, has been in the interests of health aimed at removing from industrial influences those of tender years. Simultaneously education authorities have extended the scope of their activities, and in recent years have further found it necessary to supervise the health of those attending school. The parting of the ways, the moment when the juvenile leaves school and enters upon occupation, is one of peculiar interest to the medical sociologist. Up to the present the medical profession has taken but little part in directing the future of the youth. We should, however, take our part, and no apology is needed for commenting here on what is being done, especially by Juvenile Advisory Committees. One of the most efficient efforts in this direction is described in the fifth report[1] (for the year ending July 31st, 1920) of the Juvenile Employment and Central Care Committee of Cardiff, upon which all interests concerned are represented.

The report points out that conditions have not been normal during the past year owing to the exigencies of war creating conditions which gave the younger persons too great a degree of independence; in consequence they lost the sense of fairness and responsibility, and got an inflated sense of their importance. Welfare work in factories has proved of value, but in the Cardiff area work in this direction has recently been somewhat stationary. Acting under the City by-laws, a scheme has been adopted as from July 28th, 1920, under which among other things: (*a*) morning employment of scholars on school days is prohibited; (*b*) registration at the Juvenile Employment Bureau of all child employees and employers of children is obligatory; (*c*) employment cards must be used, containing records of school time and of various subsequent employments; (*d*) the hours of possible employment are restricted to from 5 P.M. to 7 P.M. on week days, to five hours on Saturdays, and 8 A.M. to 10 A.M. on Sundays; and (*e*) the minimum age for street trading is raised to 15 years. This scheme is one of the most advantageous yet adopted, and special officers are appointed to enforce compliance with its requirements. Evidence is given in the report that abuse of child employment in the past demanded action; one instance will suffice: "I met with one case where a boy regularly had nothing to eat between 8 A.M. and 5.30 P.M. owing to being employed in the dinner hour (lad since died)." The regulation which now prevents juveniles from leaving school except at the end of the term during which they attain the age-limit, is causing some inconvenience because employers have not yet learned to arrange that vacancies shall synchronise with term-ending periods; this inconvenience is probably temporary. Visits during school hours of parties of senior scholars to works and factories have proved of value in enabling them to make a better choice of occupation. For the moment tailoring is reported to be unpopular, and to be falling to the alien population; on the other hand, mechanical trades are much sought after, probably because they are controlled by unions able to secure good remuneration and conditions.

The Juvenile Employment Bureau is increasing in popularity with girls; during the period reported upon fresh applications were received from 2731 girls as against 1780 during the previous year. The bureau arranged 148 apprenticeships for girls (44 to tailoring) as against 165 for boys; in future training for domestic service is to be a feature of the work. The figures given indicate that many juveniles are not well placed at the first trial; thus, for boys 1721 vacancies were filled, of which only 468 were first places. Girls apparently settle down easier, since out of 1280 vacancies filled 512 were first places. Unfortunately no information is given as to length of service which follows placing. Here, rather than in the number of vacancies filled, lies proof of the employment bureau's work. We hope that the committee will look into this matter and publish results, laying stress on the length of employment which follows at different trades and occupations.

URBAN VITAL STATISTICS.

(Week ended March 5th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had increased from 12·3 to 15·5 in the five preceding weeks, fell to 15·2 per 1000. In London, with a population of 4½ million persons, the death-rate was 14·8, or 0·3 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 7·1 in Edmonton, 7·6 in Grimsby, and 9·2 in Wimbledom and in Bury, to 22·4 in Wakefield, 23·4 in Cambridge, and 25·3 in West Hartlepool. The principal epidemic diseases caused 259 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 89 from infantile diarrhœa, 68 from whooping-cough, 62 from diphtheria, 20 from measles, 14 from scarlet fever, and 6 from enteric fever. Whooping-cough caused a death-rate of 1·3 in Sunderland, 1·4 in Edmonton, and 2·3 in Wigan. The deaths from influenza, which had increased from 61 to 138 in the four preceding weeks, further rose to 167, and included 45 in London, 9 in Hull, 8 in Newcastle-on-Tyne, and 6 in Leeds. There were 3738 cases of scarlet fever and 2809 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3845 and 2800 respectively at the end of the previous week. During the week ended Feb. 26th 9 cases of encephalitis lethargica were notified in the County of London, and comprised 1 each in Battersea, Bermondsey, Bethnal Green, Greenwich, Hackney, Hampstead, Kensington, Paddington, and Woolwich. The causes of 30 of the 5422 deaths in the 96 towns were uncertified, of which 7 were registered in Birmingham, and 3 each in London and Gateshead.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had increased from 14·9 to 19·4 in the four preceding weeks, fell to 18·0 per 1000. The 413 deaths in Glasgow corresponded to an annual rate of 19·6 per 1000, and included 40 from whooping-cough, 21 from influenza, 6 from infantile diarrhœa, 4 from diphtheria, 3 from scarlet fever, and 1 from measles. The 152 deaths in Edinburgh were equal to a rate of 17·8 per 1000, and included 11 from influenza, 4 from measles, 2 from diphtheria, and 1 each from whooping-cough and infantile diarrhœa.

Irish Towns.—The 153 deaths in Dublin corresponded to an annual rate of 18·9, or 0·8 per 1000 above that recorded in the previous week, and included 4 each from influenza and infantile diarrhœa and 3 from diphtheria. The 141 deaths in Belfast were equal to a rate of 17·5 per 1000, and included 10 from whooping-cough, 4 from infantile diarrhœa, and 3 from influenza.

EASTBOURNE EAR, NOSE, AND THROAT HOSPITAL. This hospital was opened at a house in Pevensey-road in the autumn of 1917. The demands made upon it soon overtaxed the accommodation, and on March 2nd last new premises were opened in Cavendish-place, the accommodation including two wards, operating theatre, consulting-room, and out-patients' waiting-room. In-patients can now be admitted, and many friends have come forward with generous help towards equipping the hospital with up-to-date appliances.

"Audi alteram partem."

CHILDREN'S DIET.

To the Editor of THE LANCET.

SIR,—I was much pleased with the kind allusion to the "Nem-System" in Professor Gowland Hopkins's Huxley lecture (THE LANCET, Jan. 1st) and with the interest taken in the research work which is being done at my clinic by Dr. Elsie Dalyell, Dr. Harriette Chick, and their assistants. Dr. Hopkins appears to consider my opinion on the question of nutrition very different from his own; I do not think that there is such a contrast. He takes a special scientific interest in the different particular foodstuffs; I have specially studied their energy value: only the combination of both our systems can solve the problem in a satisfactory way.

In order to avoid the difficulty of the separate structural elements I treated protein as an undefined substance. I require at least 10 per cent. of the Nem-quantity to be given in the form of protein. Thus, when taking an ordinary human diet into consideration, there is a probability that all the necessary kinds of the structural elements are contained in it. I must own, however, that it is only a probability. In order to be quite sure all the foodstuffs would have to be examined in order to find out their content of structural elements. In the practice of everyday life this does not seem necessary; for, in combining the customary foodstuffs of our daily fare into a diet, varied according to the difference of days and of meals, we get so large a collection of single substances that we may be quite certain of their containing structural elements of all kinds.

I must remind you of the fact that none of the nutritive systems have hitherto been based on the exact *quantity* of structural elements. If we wanted to do this we should not only have to think of protein, but also of the mineral components, such as chlorides, potash, chalk, iron, &c. At certain periods in the past doctors were rather anxious as to whether one or the other substance was contained in the food in a sufficient quantity. Think of the time when medical science thought an addition to the food of iron, chalk, or phosphorus desirable. But this has not become a lasting custom, from which fact I should like to draw the following conclusion: the food of the omnivorous of all civilised nations will rarely completely lack single structural elements that are necessary, or contain less than the minimum, so that it would not be worth while to make their calculation a daily rule. Only water, the most important element of structure, was, as a matter of principle, taken into consideration by the Nem-System. I refer to Nobel's excellent experiments,[1] an abstract of which is to be found in my "System der Ernährung," Vol. IV., p. 393, in which the laws relating to the minimum content of water in diet are explained.

It is a little different with the vitamines. Even an abundant and varied menu may be without vitamines, for example, if it is composed of preserved foodstuffs. We have made it a practical rule that the diet must contain fresh vegetables or potatoes at least once every day. This rule was based on experience, as also the rule ensuring a certain coarseness or cellulose content of the diet, which is of such vital importance for the movement of the bowels, except in the first years of babyhood. I admit that in these two cases of the vitamines and of coarse food, instead of a vague recommendation, there ought also to be a quantitative rule, expecially in a system that requires such a detailed and graduated administration of food as the Nem-System prescribes. This quantitative rule might be determined by finding out the approximate content of cellulose and of the three important vitamines in all foodstuffs and then by summing them up, determining [illegible] necessary minimum that must be present in the [illegible], as I have done in the Nem-System for protein. I shall be glad if the English workers here will make practical proposals of this kind. and I am quite willing to incorporate them in the Nem-System.

With regard to the observations that are being made by the mission of the Lister Institute at my clinic I think I can already make the following statement:—

Especially when tried on bigger children, there is no essential difference between our diets, composed according to the Nem-System, and containing at least 10 per cent. protein, and a diet purposely rich in vitamines, and this for the very good reason that diets, arranged according to the Nem-System, do not consist merely of caloric elements, theoretically calculated, but of the customary mixture of ordinary foodstuffs. For the feeding of babies, however, I hope to draw much benefit from the result of the English researches. We have been giving to the babies a rather unvaried food, and we are ill-informed as to the vitamine content of milk, which forms the chief article of their diet. It has happened more than once that infants have acquired scurvy under our eyes because we gave them a diet that was poor in vitamines. Our bigger children have only once suffered from a real epidemic of scurvy, and that was in the time of the worst malnutrition, when, owing to the war, our kitchen could not be supplied with fresh vegetables and meat. I must admit, however, that the criticism with regard to our practice of overcooking vegetables is justified and we will follow the advice given in that direction.

If at that time we had known what we are now learning from the English school of nutrition, we should not have been so inactive in providing the necessary fresh foodstuffs, contenting ourselves with the fact that they did not arrive on the market of their own accord; but, like our English colleagues, we should have tried to get the necessary foodstuffs direct from the peasants. On the other hand, I hope, our English colleagues will have learned from us how to base their observations of nutrition upon a quantitative caloric foundation. It is not possible to regulate the details of *qualitative* feeding of human beings without first having discovered the caloric requirements of the child apart from the irregularities of preparation and of the child's appetite.

Thus we may both learn from each other, and I hope that these international studies will have good practical results which will make it clear to both the British and the continental practitioners who have hitherto disregarded the vitamine theory as well as the principles of quantitative nutrition, that the results of the new work on this subject are now ready to be carried into practice.

I am, Sir, yours faithfully,
Vienna. CLEMENS PIRQUET.

⁂ Professor v. Pirquet writes from an unrivalled experience. The only adverse comment to be made upon the Nem-System is its apparent neglect of the fat supply. In the diet of children can fat be replaced by sugar of the same caloric value?—ED. L.

THE CONTROL OF BIOLOGICALS.

To the Editor of THE LANCET.

SIR,—Whilst the subject of standardisation of therapeutic substances is occupying the attention of scientists is it not incumbent upon us, in our own sphere, to remove an unnecessary inaccuracy in therapeutic usage by standardising the dosage of the product derived from thyroid gland more accurately than is at present the case? As has been pointed out elsewhere,[1] a considerable confusion has arisen in the administration of thyroid gland substance, which confusion is due, in part, to the discrepancies existing between the standard unit of dose used respectively in the British Pharmacopœia and by the commercial houses which supply the product; and, in part, to a lack of uniformity in the terms used in prescribing the substance. In the B.P. the dose is stated in terms of the dried gland; whereas, commercially, it is, with only one exception I believe, stated in terms of the fresh gland, which, bulk for bulk, contains much less of the active principle than does the desiccated substance. If thyroid tablet, gr. v., be prescribed, this can be rightly dispensed in terms either of the dried gland or of the fresh gland; and upon the same prescription a patient may receive a dose equivalent to thyroideum siccum B.P. gr. i. from one chemist and a dose equivalent to thyroideum siccum B.P. gr. v. from another chemist. This error is constantly occurring and must potentially continue so long as the two units of dosage are available; but the difficulty would be entirely overcome if the nomenclature of the B.P. only were adopted by the profession. In this connexion such terms as thyroid extract, thyroid tablet, thyroid gland, or thyroid substance have no exact meaning, and the use of them leaves the intention of the prescriber a matter of uncertainty and doubt, which is neither scientific nor conducive to attainment of the best clinical results.—I am, Sir, yours faithfully,

[1] Brit. Med. Jour., 1917, ii.

Torquay, March 5th, 1921. A. E. CARVER.

AS OTHERS SEE US.

To the Editor of THE LANCET.

SIR,—The letters on this subject in your issues of Feb. 26th and March 5th are of psychological interest. If we class our profession as a *mixed group*,[1] "partly traditional and partly purposive," its spirit appears disturbed by threats at the tradition that the interest of the patient must come first and at the purpose of ameliorating the lot of humanity. It recoils from the attempt of the commercial spirit to lower the group ideal to a selfish financial level. This is an old trouble. The strength and truth of our traditions so ably upheld by your correspondents should soon reduce it again to unimportance.

Our group spirit seems to find a threat also in the various proposals for a (whole or partial) State service of medicine. Is this justifiable? The implied object of a State service should be to further the ideal objects of the profession. Experience suggests that this might be overlooked if the service had not the advantage of an inspiring declaration of ideals from leaders like Sir George Newman and Lord Dawson. The group ideal would be obscured or annihilated if the primitive altruistic tendencies of the individual doctor were not encouraged and utilised. Crude individualism would then triumph. I gather that this has happened to some degree in the panel service.

Again, recent experience suggests that such systems tend to subdivide into (1) an administrative, (2) a clinical service. The first rules the second. They become divided sharply in sentiment and purpose. Disaster to professional ideals follows. With administration as a detached end—a thing of supervenient forms, statistics, and costs—the interests of the patient disappear, and the amelioration of the human lot sinks to a secondary level. The clinician finds himself paralysed. He may submit to see his clinical and ethical standards destroyed. He may protest and starve. Perhaps then our group spirit is rightly perturbed. It wishes to be sure that no possible State service will injure our traditions and purpose in the slightest degree. Its anxiety is not allayed by critical examination of such experiments in State service as are now in progress. Without unity of spirit and purpose no group service can flourish; without declared and re-declared ideals it must fail. Once declared, ideals spread by "example, suggestion, and emotional contagion." The responsibility of maintaining them by appeal to the group spirit lies with those who occupy positions of prestige.—I am, Sir, yours faithfully,

March 6th, 1921. H. LAING GORDON.

To the Editor of THE LANCET.

SIR,—The letter of Dr. Harry Roberts in your issue of Feb. 26th lays bare the sad position into which the profession has fallen in the esteem of the public. Can anyone wonder when the public sees how doctors treat each other? Take a striking example. There are doctors with anything from 1000 to 4000 panel patients (I write with personal knowledge), and with good private practices, increased when we were on active service, remaining on the Pensions Medical Boards, absolutely indifferent to the struggle which many ex-Service men are having to make ends meet. These doctors have apparently no qualms in competing with the hard-hit ex-Service men, though they remained at home in safety of body and security of practice.

I am, Sir, yours faithfully,

March 4th, 1921. AN EX-SERVICE MAN.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—There are two statements in Mr. J. E. Adams's letter in your issue of Feb. 19th which, I feel, call for comment: 1. That when the appendix is abnormally placed the cutaneous hyperalgesia has always been over the situation of this organ, as revealed by subsequent abdominal section. This has certainly not been my experience. I have operated upon many abnormally placed appendices, and have always found the cutaneous hyperalgesia, if present, to be over the typical "functional" area in the right iliac fossa, my observations in this respect agreeing with those of Ligat. The most striking instance was in an early case of acute appendicitis with epigastric pain, cutaneous hyperalgesia limited to the right iliac fossa, but with no deep tenderness anywhere. Operation revealed the entire absence of the cæcum, appendix, and omentum from the right iliac fossa. Eventually the cæcum and appendix were found deeply placed in the region usually occupied by the splenic flexure of the colon; the appendix was hugely and tensely distended with mucopus and its mucosa quite gangrenous. 2. That in assessing the value of clinical observations "negatives are surely of the same relative value as positives." It depends upon what one understands by "relative." As a positive clinical observation the presence of the sign of "loss of liver dullness" is of undoubted importance in the diagnosis of perforation of the alimentary canal, whereas its absence is of no value whatever in excluding such. Surely in a suspected case of early renal tuberculosis one positive finding of the tubercle bacillus in the urine is of greater value than 50 or more negative findings. As positive findings I consider the hyperalgesic "functional" areas of great value in determining the viscus primarily responsible in both acute and chronic abdominal lesions; I pay no attention whatever to negative findings. My experience is mainly with the "appendix," "gall-bladder," "gastro-duodenal," and "small intestine" areas, but last Friday night I was interrupted in my reading of Mr. Adams's letter of condemnation by a call from a practitioner in a neighbouring town to see with him an acute abdominal crisis, which we recognised as an intraperitoneal hæmorrhage from rupture of an ectopic gestation, but with absolutely no clue as to which Fallopian tube was concerned. The application of the "cutaneous hyperalgesia" test to the "functional" area for each Fallopian tube gave a most striking response on the left side, and at the operation the left tube was found to be the one ruptured.

I am, Sir, yours faithfully,

Manchester, Feb. 21st, 1921. ARTHUR H. BURGESS.

VITAMINES AND COMMON SENSE.

To the Editor of THE LANCET.

SIR,—Professor W. D. Halliburton, in the course of his letter on this subject in THE LANCET of March 5th, takes the opportunity of raising again the much-debated question of heated *v.* unheated milk. He says that he cannot see that "the simple process of pasteurisation is the danger that some extremists allege it to be from the point of view of vitamines." This, no doubt, is true as far as the vitamines are concerned, but Professor Halliburton has forgotten one or two essential facts in the biological properties of milk and of the infant. Escherich and Baginsky showed over 30 years ago that there is a direct antagonism between the fermentative and putrefactive organisms in the child's intestine, and Bienstock in 1901 demonstrated the fact that raw milk cannot be made to putrefy by inoculating it with putrefactive germs, whilst if the fermentative germs are destroyed by heating the milk putrefaction at once takes place.

---

[1] The Group Mind, by McDougall, 1920, p. 92.

Since these observations were first made numerous investigators have studied the problem and have in the main confirmed the results, but recently Lorenz described an outbreak of Y dysentery in a Hamburg orphan asylum, which he believes, as the result of clinical and experimental evidence, to have originated from boiled milk infected with *Bacillus dysenteriæ Y* in the orphanage kitchen. It is true that pasteurisation will afford some sort of protection against such diseases as diphtheria, scarlet fever, and enteric, but taking into consideration the fact that young infants are more or less immune against such diseases in virtue of their harbouring a considerable number of immune bodies transferred to them by the mother during their intra-life, the danger of communicating such diseases during non-epidemic periods, at any rate to very young infants, is almost insignificant. Whilst therefore the risk of conveying infectious diseases by means of raw milk is very slight, the danger of setting up intestinal putrefaction in infants on administering heated milk is very considerable.

I am, Sir, yours faithfully,

London, W., March 7th, 1921. W. M. FELDMAN, M.D.

DANGEROUS DRUGS ACT, 1920.

To the Editor of THE LANCET.

SIR,—A perusal of the Draft Regulations, made under the Dangerous Drugs Act, 1920, indicated they were rather unsuitable for hospital practice for reasons which need not now be stated. Representations were therefore made on behalf of hospitals, and a series of interviews took place at the Home Office at which the question was fully discussed, with the result that special regulations are being evolved which should prove quite acceptable to these institutions.

Although it is at the moment not permissible to give details, yet it may be stated that these new regulations will not add to the duties of the members of the medical and surgical staffs, and that for the hospital pharmacist they will involve very little more than the adaptation of the existing organisation of the hospital dispensary to meet a special set of circumstances.

I am, Sir, yours faithfully,

F. A. HOCKING,

March 3rd, 1921. Pharmaceutist to the London Hospital.

To the Editor of THE LANCET.

SIR,—The Council of the London and Counties Medical Protection Society, Ltd., which represents over 6000 members of the medical and dental professions, at its last meeting decided to offer strenuous opposition to the proposed Regulations under the Dangerous Drugs Act, 1920.—I am, Sir, yours faithfully,

HUGH WOODS,
General Secretary, London and Counties Medical Protection Society, Ltd.
Craven-street, Strand, W.C., March 4th, 1921.

PSEUDO-COXALGIA.

To the Editor of THE LANCET.

SIR,—I should like to associate myself with some of the remarks of my friend, Mr. A. S. Blundell Bankart, on the nature of the "recovery" in pseudo-coxalgia. It is true that in this disease during childhood, with a radiographic picture showing an extreme deformation of the head of the femur, there may be a complete absence of limp and shortening, and the limitation of abduction may at the moment in no way cause any true disability. Out of 17 cases I have under observation at the present time this grade of "recovery" is present in eight. But it is essential to remember that such an alteration in the mechanics of the hip-joint is likely to produce trouble in adult life. The radiographic end-result in these cases is an enlarged flattened head which is far too big for the acetabulum. This is shown quite conclusively in a number of my radiograms of hip-joints in adults who give a clear history of pseudo-algia in childhood. In later life such hip-joints wear and tear badly, and may progress towards steo-arthritic stage. The limitation of abduction w a serious defect.

For this reason I hold with Mr. Bankart that it is advisable to treat all cases of pseudo-coxalgia in the early stage by complete relief from weight-bearing, and, further, to maintain for a considerable time the position of abduction. This was originally recommended by Mr. Muirhead Little in 1915. I must confess that in my earlier cases I adopted a laissez-faire attitude, but in my more recent cases I have felt constrained to treat them as one does the initial stages of true tuberculous arthritis.

I am, Sir, yours faithfully,

Manchester, March 5th, 1921. HARRY PLATT.

To the Editor of THE LANCET.

SIR,—Mr. A. S. Blundell Bankart has done service to many patients by pointing out that in the above condition the advice, "No treatment is necessary," is wrong. Because the disease is not the ordinary hip disease, and may not be tuberculous, surgeons have hastened to excuse their patients from prolonged and perhaps irksome immobilisation, with regrettable results in shortening, limitation of movement, and consequent limp. Mr. Bankart, I think, is not alone in the method of treatment he adopts. Dr. Rollier, in his heliotherapy clinic at Leysin, has for years given up making any distinction as regards treatment between these cases and the ordinary cases of hip disease. All alike are treated by recumbency and extension until a radiogram shows regeneration of the head of the bone.

I am, Sir, yours faithfully,

Harley-street, W., March 5th, 1921. PAUL BERNARD ROTH.

TREATMENT OF DIPHTHERIA CARRIERS.

To the Editor of THE LANCET.

SIR,—In bringing my correspondence on the above subject to an end, I thank Dr. A. G. B. Duncan for recapitulating his "views and intentions" (THE LANCET, Feb. 26th, p. 459). Let me say that I still find myself unable to appreciate the necessity for his differentiation between "carrier" and "positive throat," and my hope is that with the more universal application of vaccine therapy (which Dr. Duncan agreed was effective in the "positive throat") the necessity will no longer arise for the term "carrier," as it does not appear wise to allow any "positive throat" to persist for such a length of time as would warrant the former "distinction." It would be matter for real regret if inaction in the first instance provided material for future experiment.—I am, Sir, yours faithfully,

JAMES LAW BROWNLIE.

Glasgow Corporation Laboratory, March 5th, 1921.

THE INTERNATIONAL UNION AGAINST TUBERCULOSIS:

A CONFERENCE IN LONDON.

To the Editor of THE LANCET.

SIR,—The next International Conference will be held in London from Tuesday, July 26th, to Thursday, July 28th, inclusive. The Conference will be open to members of the International Union against Tuberculosis and to delegates from countries within the League of Nations, and from the United States of America. The president of the International Union for the current year is Mons. Léon Bourgeois, President of the French Senate, who will be succeeded on the occasion of the Conference in London by Professor Sir Robert Philip of the University of Edinburgh. It is hoped that the opening address of the Conference will be given by Mons. Léon Bourgeois. The arrangements for the Conference are under the charge of the executive committee of the International Union in correspondence with the Council of the National Association for the Prevention of Tuberculosis.

The subjects proposed for discussion include the following: (1) The Modes of Diffusion of Tuberculosis throughout the Races of the World, to be opened by Professor Calmette; (2) the Rôle of the Medical Profession in the Prevention of Tuberculosis.

In the name of the International Union,

I am, Sir, yours faithfully,

LEON BERNARD,
March 3rd, 1921. Secretary.

Obituary.

SIR FELIX SEMON, K.C.V.O., M.D. BERLIN, F.R.C.P. LOND.,

SOMETIME PHYSICIAN FOR DISEASES OF THE THROAT, ST. THOMAS'S HOSPITAL.

Sir Felix Semon, who died at his residence, Great Missenden, Bucks, on March 1st, at the age of 72 years, was the son of a Berlin stockbroker, and was educated at Heidelberg, where his medical studies were interrupted by the Franco-Prussian War in which he served as a volunteer. Graduating M.D. Berlin in 1873 and obtaining the German States Diploma in the following year, he continued his medical studies in Vienna and Paris, devoting special attention to diseases of the throat on which the introduction of the laryngoscope was throwing a flood of light. Finally he came to London and entered at St. Thomas's Hospital, becoming in 1875 clinical assistant at the Throat Hospital in Golden-square. He was admitted a Member of the Royal College of Physicians of London and was elected a Fellow in 1885. In 1877 he became physician at the Throat Hospital, in 1882 physician in charge of the Throat Department at St. Thomas's Hospital, and in 1888 laryngologist to the National Hospital for Epilepsy, Queen-square.

His outstanding contributions to laryngology are his work on laryngeal paralysis and that on malignant disease of the larynx. The former research, begun in 1878, extended over a great number of years and was the subject of numerous papers. As a result there was established the law that goes by Semon's name regarding the proclivity of the abductors to paralysis in lesions of the nerve trunks and centres. Further researches both on his own account and with the late Sir Victor Horsley did much to elucidate the central motor innervation and showed, among other things, that it is probably impossible for a one-sided cortical lesion to produce laryngeal paralysis. As a result of these and other researches a most valuable generalisation was arrived at—namely, that laryngeal paralysis which involves the abductors (sometimes in association with the adductors, it is true) is due to organic disease, whilst motor paresis of the adductors is in the large majority of cases functional, more rarely myopathic, and then usually due to catarrh. Semon's work on malignant disease of the larynx was begun at a time when the subject was in a chaotic state. He first established the fact that of all parts of the larynx the cords were most liable to be attacked. His next undertaking was an investigation of symptoms and appearances facilitating the early recognition of the disease, and finally, with regard to the treatment of the condition, he advocated and practised the operation of laryngo-fissure which Sir Henry Butlin was beginning to revive as a result of Semon's work.

In addition to his neurological work and that on malignant disease Semon made numerous contributions which are collected in his two volumes, "Forschungen und Erfahrungen," published in 1912. Of these, the most important from a clinical point of view would seem to be the one concerning septic infections of the throat entitled, "On the Probable Pathological Identity of the Various Forms of Acute Septic Inflammation of the Throat and Neck hitherto described as Acute Œdema of the Larynx, Œdematous Laryngitis, Erysipelas of the Pharynx and Larynx, Phlegmon of the Pharynx and Larynx, and Angina Ludovici." His presentment of the clinical picture was striking, and his conclusions have since proved sound. Another paper of permanent value is entitled, "The Therapeutic Value of Complete Vocal Rest during Sanatorium Treatment of Laryngeal Tuberculosis." His advocacy of this method of treatment did much to bring about its employment at every sanatorium.

Semon's work for laryngology was not, however, only scientific. He devoted a large amount of time to the advancement of the position of the specialty, and did a great deal to bring about its recognition as an important section of surgery. In 1884 he originated the *Centralblatt für Laryngologie* and edited it for 25 years, making it a most valuable publication. In 1893 he founded the Laryngological Society of London, and later helped it to become, as a section of the Royal Society of Medicine, a virile organisation. As a delegate at international congresses he continued to uphold his view of the specialty, and I think it may fairly be said that each step of his career was marked by an increase of the esteem in which British laryngology in general was held by the medical profession.

Sir Felix Semon's reputation as laryngologist brought him many honours, and he held the honorary presidency or fellowship of laryngological societies of the principal countries of the world. In 1894 the German Emperor conferred on him the title of Royal Prussian Professor and in this country at the Diamond Jubilee in 1897 he received the honour of knighthood, and in 1902 the C.V.O. from which he was promoted to K.C.V.O. in 1905. In 1901 he became Physician Extraordinary to King Edward VII. On his retirement from London in 1911 British and foreign laryngologists testified their esteem by the gift of a purse containing £1010, which he presented to the University of London for the establishment of "The Semon Lecture Trust."

Of Semon's personal attributes Dr. F. de Havilland Hall, one of his oldest friends, writes:—

"Semon was of a singularly affectionate nature, and though quick-tempered his wrath was soon over, and his sunny nature reasserted itself. That which first inspired me with admiration for his ability was the masterly way in which he managed the subsection of laryngology at the great International Medical Congress held in London in 1881, when the late Dr. James Walker, of Peterborough, and I were his colleagues. At the beginning of each sitting Semon gave out in English, French, and German the programme for the morning, and also added a few words in Italian. For many years his neighbour, I had the fullest opportunity of seeing how honourably he acted up to the best professional ethics. On all sides I heard of his skill and kindness. Mention should be made of his musical gifts. While encamped outside Paris in 1870-71 he composed a march to the strains of which his regiment of Uhlans entered Berlin after peace was declared. One of the great treats of his friends was to hear him accompany his wife, who was a celebrated vocalist. He was also devoted to hunting, shooting, and fishing, and his friends will remember him for the staunchness of his friendship and his loving nature."

Of his three sons, all of whom held commissions in the British army, one is a medical man—Dr. Henry Semon, physician for diseases of the skin to the Great Northern Hospital.

THE LATE DR. J. WILSON ADAM.—The death took place at Aberdeen on March 5th of Dr. J. Wilson Adam, a well-known local practitioner. Dr. Adam, who was 61 years of age, was a very active man. During the war he did much relief work, and this, added to his own large practice, told severely on his health. He was suddenly seized with illness on March 1st, and never rallied. Dr. Adam was a son of the late Mr. John Adam, of Aberdeen. He graduated M.B., C.M. at Glasgow University in 1890 and started practice at Tarbolton, Ayrshire, where he remained for ten years. He returned to Aberdeen in 1900 and soon built up a large practice. He was at one time medical officer to the Aberdeen Dispensary. Dr. Adam is survived by a widow and a large family.

THE LATE DR. J. E. BULLOCK.—The death has occurred from pneumonia of Dr. J. E. Bullock, of St. Leonards, at the age of 67. He was educated at University College Hospital, and practised for many years at Ladbroke-grove, London. More recently he took up the special study of tuberculosis, and was for some time on the staff of the Eversfield Chest Hospital, St. Leonards-on-Sea. During the last period of the war he was engaged as tuberculosis medical officer for Northamptonshire. It was when filling a temporary vacancy there that he met his death. He translated Cornet's work, "Skrofulose," with marked success, and published numerous articles in the medical journals. He was recognised by all who knew him as a man of high character and extensive knowledge of medicine, kind and painstaking with his patients, and he will be greatly missed by a large circle.

Parliamentary Intelligence.

HOUSE OF COMMONS.

MONDAY, FEB. 28TH.

Dentists Bill.

Dr. ADDISON informed Mr. F. THOMSON that he was not in a position to name any definite date for the introduction of the Bill to amend the Dentists Act, 1878, but if there was a general desire in the House that the Bill should be introduced without delay, and if it would be treated substantially as an agreed Bill, the Government would be prepared to introduce it in the House of Lords at an early date.

TUESDAY, MARCH 1ST.

Feeding of Children in Central Europe.

Mr. KELLAWAY (Secretary to the Department of Overseas Trade) informed Sir H. BRITTAIN that British institutions were feeding over a quarter of a million children daily in Central Europe, and he was informed, though he could not vouch for the accuracy of the figures, that 2,750,000 children were being fed under the auspices of the American relief administration, and further numbers of children by other American organisations.

Remuneration of Panel Practitioners.

Captain Sir DOUGLAS HALL asked the Minister of Health if it was proposed to increase the remuneration of panel doctors owing to the burden of increased work which was thrown upon them in connexion with the compilation of the new medical records; and whether such increased remuneration would be met by larger insurance payments or smaller benefits, or whether it would fall upon the general taxation of the country.—Dr. ADDISON replied: The keeping of medical records has always formed part of the terms of service of insurance practitioners, and was taken into account when the rate of remuneration was settled by arbitration last year. No question, therefore, of increasing the remuneration arises.

Medical Men and the New Medical Records.

Captain Sir DOUGLAS HALL asked the Minister of Health whether his attention had been drawn to expressions of opinion which had recently been uttered by medical men and representatives of the profession regarding the uselessness, in a statistical scientific view, of the information which it was proposed to collect from the new records of insured patients; and whether, in face of that adverse opinion, he would withdraw the new rules and so prevent further waste of taxpayers' money and medical men's time, and the irritation of the working classes.—Dr. ADDISON replied: I am aware that some individual medical practitioners have criticised the form of medical record presented under the insurance terms of service, but nearly four-fifths of the members of the Departmental Committee, presided over by Sir Humphry Rolleston, which designed the form of the record, were members of the medical profession, and had regard not only to the statistical scientific uses of the records, but also, and indeed mainly, to their utility in the treatment of insured persons. The Panel Committees, which are the statutory bodies appointed to express the views and wishes of insurance practitioners, have decided, not unreasonably, to defer any formal expression of opinion in regard to the records until the insurance practitioners have had adequate experience of the arrangements.

WEDNESDAY, MARCH 2ND.

Medical Man's Indian Contract.

Mr. THOMAS GRIFFITHS asked the Secretary for India whether he was aware that Dr. A. D. Denning, of Stafford, entered into a contract with the Indian Government for five years' service in India; that at the end of three years the contract was terminated on medical grounds which were afterwards found to be erroneous; that subsequently it was claimed and upheld that, despite any contract, the services of a servant could be terminated at the will and pleasure of the Crown; that the India Office had since granted Dr. Denning £500, which was not sufficient to cover his costs in the legal action, and that consequently Dr. Denning was without compensation for the loss of his appointment; whether this case would have further consideration; and whether, in order that men of ability might be encouraged to enter into these contracts, he would consider the advisability of abandoning the claim that service could be terminated at the will and pleasure of the Crown.—Mr. MONTAGU replied: The facts referred to in the first two parts of the question are generally as stated, except that edical grounds on which Dr. Denning's contract was ed were not found to be erroneous. As regards part of the question, Dr. Denning subsequently an action for breach of contract, or, in the alternative, for wrongful dismissal; the Secretary of State for India in Council contended that Dr. Denning's service was *terminated in accordance with his agreement by which he* undertook to obey the rules prescribed for his branch of the public service; these rules provide for the termination of an officer's duty on grounds of ill-health; but the case was settled on a preliminary point of law that no action can lie against the Crown for the termination of such service at the pleasure of the Crown; in view of certain comments made by Mr. Justice Bailhache on the form of the agreement (an old form which was altered some years ago), Dr. Denning was granted, by the Secretary of State for India in Council, £500 on account of his costs; I am not aware that this sum is insufficient for the purpose, nor that he has any claim, on the merits, to compensation for the loss of his appointment. I do not think that this particular case calls for further consideration. As regards the last part of the question I am advised that it would be improper to introduce in the contracts referred to any words purporting to limit the right of the Crown to dispense with the services of its officers, but this right would naturally be used, if at all, only in very exceptional circumstances.

Security of Tenure for Medical Officers.

Sir PHILIP MAGNUS asked the Minister of Health what progress had been made in giving effect to the promise made in his letter of May 21st, 1920, in pursuance of a previous promise of the Local Government Board, to proceed with an Order to give security of tenure to whole-time medical officers and to his proposal to include sanitary inspectors and inspectors of nuisances in the Order on the same terms.—Dr. ADDISON replied: This matter has been under consideration. I am advised that legislation would be required to give security of tenure to existing officers, and the Order which will shortly be issued must therefore be confined to new appointments of the classes mentioned.

Public Health Officials at Bromley.

Dr. ADDISON, in reply to Lieutenant-Colonel JAMES, stated that the whole-time public health staff employed by the Bromley borough council consisted of two inspectors of nuisances and two health visitors, acting under the general supervision of the medical officer of health. There were in addition certain officers employed on school medical services. The appointment of a medical officer of health rested with the borough council and the original proposal to employ a whole-time medical officer of health came from them. In addition to performing the duties of medical officer of health the officer in question would act as supervising school medical officer and would be in charge also of the maternity and child welfare work of the borough. He was advised that the proposed arrangement would be both economical and useful, and he did not therefore see his way to withhold his general approval of the proposal. The only protest he had received was from the honourable and gallant Member himself.

Medical Record Cards.

Mr. FORREST asked the Minister of Health whether he was still receiving any protests from panel doctors as to the work entailed by filling up the new forms of cards; and, seeing that the time so employed diminished the amount of attention which could be given to individual patients, would he inquire into the whole matter to see how the system is working.—Dr. ADDISON replied: I would refer the honourable Member to the answers to the questions which I gave yesterday on the subject of the medical record cards to Captain Sir Douglas Hall. I cannot accept the view that the keeping of records must detract from the time available for giving adequate medical treatment. In the majority of insurance practices the practitioner is responsible for less than one-fourth of the number of insured patients for which, in the view of the doctors' own representatives, an ordinary practitioner can safely assume responsibility. I may say that the number of objections to the record cards from medical men and others concerned in working the system is insignificant. Out of some 150 Panel Committees, representing some 12,000 medical men on the panel, I have only received protests from 9, and those are mostly on points of detail, although every effort has been made to stir up *discontent in this matter by certain persons.*

The Spahlinger Treatment of Tuberculosis.

Mr. DEVLIN asked the Minister of Health whether the British Consul at Geneva recently sent to the Foreign Office a communication calling attention to the new treatment for tuberculosis, known as the Henri Spahlinger's method; whether this communication had been referred to him; whether eminent medical specialists in Switzerland, France, and other countries had testified to the remarkable percentage of cures effected by this treatment; what action, if any, the Department of Health had taken in this matter; and whether, in view of the attempts to stamp out this scourge, which levied such a heavy toll of lives in Great Britain and Ireland annually, he was prepared to say that a full and prompt official medical investigation of this new treatment would be held.—Dr. ADDISON replied: I am aware of the communication to which the honourable Member refers. It appears that so long ago as 1913 to 1914 the serum in question was prepared and the matter was carefully explored by the Medical Research Council and by independent physicians, but the trials have not been sufficiently exhaustive to justify any definite and reliable conclusions. If and when supplies of the serum become available in this country I will certainly see that its efficacy is exhaustively tested. But I understand that a supply of the serum is not likely to be available for this purpose for some months, and that on account of the secrecy maintained as to its constitution and method of preparation it has hitherto been found impracticable for the recognised research laboratories in this country to investigate its properties and effects.

Fraudulent Cures.

Captain TUDOR-REES asked the Minister of Health whether his attention had been called to the advertisements of alleged cures for cancer and other diseases; and whether, with a view to protecting the public from the frauds and deceptions of these advertisers and from the ill-effects of their supposed remedies, he would introduce legislation to render such advertisements illegal.—Dr. ADDISON replied: The Proprietary Medicines Bill, which was introduced last session, was intended to give effect to the recommendations of the Select Committee which reported on this question in 1914. The Bill is now being revised to meet certain objections of the commercial interest concerned, and I hope it will be possible to reintroduce it during the present session, but I am unable at present to give any definite date.

Venereal Disease and Self-disinfection.

Lieutenant-Colonel FREMANTLE asked the Minister of Health whether his attention had been called to the Report of the Special Committee on Venereal Disease recently published, and to its recognition of the value of immediate self-disinfection; and what steps were proposed to be taken by his Department in the matter.—Dr. ADDISON replied: Yes, Sir. The matter to which my honourable and gallant friend refers is now under consideration, and all the relevant documents and evidence, including the Report mentioned, will be considered.

Maternity and Child-Welfare Centres.

Dr. ADDISON, replying to Sir K. FRASER, said that according to the last available information 43 persons (of whom 25 were men) were appointed during 1920 specifically as medical officers of maternity and child-welfare centres, the rate of remuneration not exceeding £1 11*s.* 6*d.* per session, and amounting in the aggregate to £3660 per annum. In addition 36 persons (of whom 10 were men) were appointed by local authorities during this period as whole- or part-time medical officers for maternity and child-welfare work generally at salaries ranging from £150 to £750 per annum. Their duties included in every case more or less direct supervision of the work of centres, but it was not possible to make any apportionment of their salaries to that specific purpose or to estimate even approximately what proportion of the total annual cost of welfare work was attributable to this branch of the service. Milk, and in special circumstances other food, might be provided at less than cost for expectant and nursing mothers and for children under 5 years of age where such provision was certified by the medical officer of a centre or by the medical officer of health to be necessary and where the case was necessitous.

Industrial Fatigue Research Board.

Mr. MILLS asked the Minister of Health whether his attention had been drawn to the decision of the Treasury to withdraw financial support from the Industrial Fatigue Research Board, and suggesting that any important work on hand might be transferred to industrial or voluntary organisations; whether he was aware of the valuable work done by the Board since its inception in 1918; that there were no organisations in existence capable of taking over the Board's work; that if the Treasury decision was carried out the last year's work of the Board would be wasted; that it would result in a set-back in the whole movement of the study of human efficiency, and would involve the discharge of about 20 investigators who had specialised in the work; and whether, having regard to all the circumstances, the Treasury decision would be reconsidered.—Dr. ADDISON replied: The expenditure on the Industrial Fatigue Research Board is naturally being reviewed with all other public expenditure in the light of the imperative need for economy. The Board itself will in any case be continued, and I think I can safely promise that sufficient funds will be provided to secure its efficiency. The Government are very fully alive to the considerations mentioned by the honourable member.

The Question of Attributability.

Lieutenant-Colonel Sir JOHN HOPE asked the Minister of Pensions whether, in the case of a soldier who was passed into the service as fit for general service and served overseas and on discharge was declared by a medical board to be unfit for general service, the burden of proof as to whether the disability was attributable to or aggravated by service lay on the soldier or on the Ministry.—Mr. IAN MACPHERSON replied: In the circumstances stated the burden of proof would lie on the Ministry rather than on the man. The fact that the man had gone overseas fit, and returned unfit, would raise a presumption that his unfitness was due to his service, and unless there was good evidence, on the facts of the particular case, that it was not so due, the Ministry would accept the liability.

THURSDAY, MARCH 3RD.

Disability Pension Awards.

Captain REGINALD TERRELL asked the Minister of Pensions how many cases there had been in which an ex-Service man or his widow had claimed a pension which had been refused on the ground that the disability was not the result of war service; and whether he was aware of the dissatisfaction which some of these decisions were causing.—Colonel GIBBS (Lord of the Treasury) replied: The number of cases in which pension has been refused to an ex-Service man on the ground that the disability was not due to service was 257,000. In the case of widows the records of the Ministry do not show refusals before April 1st, 1920. The number of rejections since that date is 6900. In all cases of refusal, whether of men or of widows, there is a right of appeal.

Mr. TREVELYAN THOMSON asked the Minister of Pensions if he was aware of the dissatisfaction felt both by local pensions committees and by ex-Service men as regards the awards of disability pensions; and could he see his way to recommend the Government to so remodel the present system as to ensure a greater feeling of confidence in the public mind with the ultimate awards.—Colonel GIBBS replied: I am not aware of any grounds for dissatisfaction with the present system under which pensions are awarded in accordance with the amount of disablement due to service, the man having the right of appeal to a medical appeal board on the question of assessment and to an independent tribunal on the question of attributability.

Mr. WATERSON asked the Minister of Pensions whether he was aware that many demobilised Service men had died from various diseases which they had contracted during war service, the final stages only developing in civilian life; if anything could be done for the widows and children of such deceased men beyond the appeal to the House of Lords Appeal Tribunal; and if he would state the number of such appeals dealt with, stating the number successful or otherwise.—Colonel GIBBS replied: The Appeal Tribunals have heard and decided 1978 appeals lodged by widows against decisions by the Ministry that the disease from which the husband died was not contracted in or aggravated by his service. Of these appeals 523 were allowed and 1253 rejected. The decisions of the Tribunals are declared by the War Pensions (Administrative Provisions) Act, 1919, to be final.—Mr. WATERSON: Is the honourable gentleman aware that many of these appeals that have gone to the Appeal Tribunal have been turned down thereby inflicting great hardship on the widows, particularly when the doctor's certificate of death certifies that the disease was contracted during military service.—Colonel GIBBS: These Appeal Tribunals consist of one doctor, one lawyer, and an ex-Service man.—Mr. LAWSON: Does the Tribunal consider the man's medical sheet during his service, and is due weight given to the local medical man's opinion?—Colonel GIBBS: I must ask the honourable Member to put any question down.—Dr. MURRAY: As the honourable and gallant gentleman cannot answer, why is not the Minister of Pensions here. Is he electioneering?—No answer was given.

Pension Suspensions.

Major GLYN asked the Minister of Pensions whether he was aware that in the event of a dependent entering a rate-aided institution, for instance, a lunatic asylum, the pension to which such an individual was entitled was suspended during such period as the dependent remained an inmate of the institution; whether the ratepayers under these circumstances in fact had to shoulder a responsibility that was really the State's obligation; and whether, in such circumstances, he would consider the desirability of providing that in lieu of suspension of the money to which the individual was entitled it should be paid to the local authorities in relief of the rates until the inmate emerged from such an institution.—Colonel GIBBS: The facts are substantially as stated in the first part of the question. The matter is at present under consideration.

Mortality from Tuberculosis.

Lieutenant-Colonel RAW asked the Minister of Health whether the exposure and hardships to which large numbers of healthy men were subjected to on active service had resulted in an increase in the mortality from tuberculosis.—Dr. ADDISON replied: Although the conditions of acti service no doubt increased the mortality from tuberculosis in weakly men and in those already suffering from tuberculosis, I am advised that there is no evidence to show that there has been an increased mortality from this disease among men who were healthy on entering upon naval or military service. I am glad to say that the latest statistics indicate that there was in 1919 a very large decrease in the number of deaths from tuberculosis in England and Wales, including both pulmonary and non-pulmonary forms; the figures for 1919 being 46,312, as compared with 58,073 in 1918 and 55,934 in 1917. I am glad also to say that the figures for 1920 so far as they are at present available indicate another decrease.

Housing and Tuberculosis Bills.

Dr. ADDISON informed Mr. Ormsby-Gore that he proposed to reintroduce the Housing Bill and the Tuberculosis Bill before Whitsuntide. He was not at present able to say whether he would introduce any other Bills affecting public health or local administration this session.

MONDAY, MARCH 7TH.

Disability Pension Awards.

Lieutenant-Colonel Sir JOHN HOPE asked the Minister of Pensions whether in assessing disability percentage medical boards took into consideration a soldier's previous occupation or trade in which he was skilled; and if a miner who had a stiff knee which would prevent him working at the coal face would be assessed at the same percentage of disability as a soldier who had been employed in a sedentary occupation, and in whose case a stiff knee would not force him to learn and take up a new occupation.—Mr. IAN MACPHERSON replied: The flat rate disablement pension is awarded without reference to previous occupation. In substitution for it, however, and subject to the conditions stated in the Warrant, a man may claim an alternative pension which is based on actual loss of earning capacity, having regard both to his former occupation and to that which his disablement permits him to follow.

Insurance Medical Records.

Mr. MYERS asked the Minister of Health whether he had received any complaints regarding the new form of medical card under the National Health Insurance scheme; whether he was aware that objection was taken to the new card on the ground that it was too inquisitorial; and whether he would give this objection his consideration.—Dr. ADDISON replied: The number of complaints which I have received about the insurance medical records is quite insignificant, consisting of representations from five only out of 10,000 approved societies and branches, none from any of the insurance committees, and nine, mainly on points of detail, out of the 150 panel committees representing the medical men on the panel. The card is in substitution for two others used since the commencement of the Act and has been designed mainly to give to insured patients the advantages enjoyed by private patients in those practices where doctors keep records, and are thereby enabled to be guided in treating current symptoms by reference to the patient's previous medical history.

Mr. D. HERBERT asked if at least one of the cards to which the right honourable gentleman referred was given up because it was found practically impossible for the doctors to keep it.—Dr. ADDISON: That is quite true; that is one of the reasons why the revised card was designed. The old card was quite useless.—Mr. D. HERBERT: Am I to understand that the new card is supposed to give the doctor less trouble than the old one?—Dr. ADDISON: It certainly gives him much less trouble. I will send the honourable Member a copy.—Mr. D. HERBERT: I have seen and studied one of these cards with several doctors, who take a different view.—Dr. ADDISON: It was designed by doctors, and mainly panel practitioners, with a view to assisting themselves in their work. It is not an invention of mine.—Sir W. H. DAVISON asked if any of the members of the medical profession were consulted before the card was issued?—Dr. ADDISON: I have said that the card was designed by a committee consisting solely of members of the medical profession—a large percentage of them being men in insurance practice.

Standardisation of Potent Drugs.

Sir J. D. REES asked the Minister of Health whether he was devising a series of expensive measures relating to the control of sera and therapeutic substances, including a controlling authority, a big central laboratory, and other machinery, in consequence of a report of a recent departmental committee appointed to consider that subject.—Dr. ADDISON replied: My honourable friend's question clearly refers to a report contained in a leading article of the *Times* of Friday, Feb. 25th. There is no truth in the suggestion that I am devising any measures of the kind indicated. From 1909 onwards suggestions have been made by the General Medical Council and other influential bodies for some hods for securing a certain measure of standardisation era and other potent drugs and substances which ot be tested by ordinary chemical means. In this I may say the responsible drug-manufacturing firms appear to concur, and it must be remembered that some of these substances are made abroad as well as in this country. The Committee reported to me during January of this year, and the chairman, Sir Mackenzie Chalmers, on his own responsibility suggested a draft Bill. When the matter came before me in January I took the view that action on the lines indicated of the proposed Bill was not practicable. So far as I have examined the subject, the Committee appeared to contemplate that the Medical Research Council, which already has laboratory equipment, should supervise the carrying out of whatever tests might prove to be required. No action whatever has been taken upon the report or any recommendations made to my colleagues, and the intentions attributed to myself to which my honourable friend refers are entirely fanciful.

TUESDAY, MARCH 8TH.

Medical Practitioners and Drug Regulations.

Major BARNETT asked the Secretary for the Home Department whether the draft regulations proposed to be issued under the Dangerous Drugs Act, 1920, required all persons dealing in morphine, cocaine, ecgonine, and heroin to keep four separate and distinct poison books, to enter in such books from day to day particulars of drugs purchased and of drugs supplied, and to make returns to the Secretary of State from time to time, and as and when required, of drugs so purchased and stocks held; and, if so, whether he would consider the desirability of exempting duly qualified medical practitioners who dispensed their own prescriptions from regulations which must necessarily prove irksome and oppressive, and involve an intolerable tax upon their time.—Mr. SHORTT replied: I have received representations from the British Medical Association as to the records which would require to be kept by medical practitioners who dispense their own prescriptions, and I have communicated to them certain modifications which I should be prepared to make in the draft regulations. The matter is still under consideration.

Major BARNETT asked the Secretary for the Home Department whether the draft regulations proposed to be issued under the Dangerous Drugs Act provided that any package or bottle containing certain specified drugs should have plainly marked upon it the name of the drug and the amount which it contained, whether the effect of this provision would be to give patients information which, in many cases, it was desirable that they should not possess; and, if so, whether he was prepared to exempt from its operation the prescriptions of duly qualified medical practitioners.—Mr. SHORTT replied: I have received representations from the British Medical Association on the point and have informed them that I am willing to agree to the exception suggested.

Farmers and Drug Regulations.

Mr. KILEY asked the Secretary for the Home Department if he would state in what way he proposed to provide, under the Dangerous Drugs Act Regulations, for farmers to procure drugs coming under the regulations for the use of their cattle; whether he proposed that such cattle medicines should be denaturised; and, if so, whether the Chancellor of the Exchequer had been consulted.—Mr. SHORTT replied: The whole question, including a suggestion as to the possibility of denaturing the drugs supplied for use by farmers, is under consideration, but I am not in a position to make any statement at present.

Insured Persons and Sanatorium Benefit.

Mr. WIGNALL asked the Minister of Health whether, now that sanatorium benefit had been eliminated from the health insurance scheme, he could state when it was proposed to take the necessary action to carry out the pledge that insured persons would not suffer any deprivation of the benefit.—Dr. ADDISON replied: The date fixed for the termination of sanatorium benefit in England and Wales is April 30th next, and I am hoping to introduce shortly a Bill dealing with the arrangements to be made for the treatment of tuberculosis after that date.

Pension Appeals.

Mr. CAPE asked the Minister of Pensions how many appeals had been heard by the House of Lords Appeal Tribunal during the period Feb. 28th, 1920, to Feb. 28th, 1921; and how many of the tribunal decisions had been in favour of the applicants and how many against.—Mr. IAN MACPHERSON replied: The number of appeals heard by the Pensions Appeal Tribunals during the period stated was 14,487. Of this number, 4384 were allowed and 10,103 rejected.

Cost of Medical Pensions Administration.

Lieutenant-Commander KENWORTHY asked the Minister of Pensions what was the total annual cost of the administration of the Ministry of Pensions divided into general and medical, the number of pensioners, exclusive of widows, children, and dependents, in receipt of disability pensions on August 1st, 1920, and on Feb. 1st, 1921, and the sums paid to these disabled men at these rates; the annual expenditure incurred in respect of the medical boards for examining disabled pensioners, the amount of the salaries and fees paid to whole-time medical officers and part-time medical officers engaged on this duty; how many whole-time medical officers were employed by the Ministry on August 1st, 1920, and on Feb. 1st, 1921; how many disabled men who were in receipt of disability pensions on August 1st, 1920, had now ceased to draw pensions by reason of death, being settled by gratuity or a final weekly allowance in lieu of pensions, and of their disability having become less than 20 per cent.; how many disabled men were in receipt of disability pensions of 20 and 30 per cent.; and what was the Parliamentary authority, if any, for the constitution of medical boards composed of three medical men.—Mr. MACPHERSON replied: The expected total annual cost of administration for the current year approximates to £6,500,000, £3,000,000 of that amount relating to general administration, £2,300,000 to medical services, and £1,200,000 to Local War Pensions Committees. The number of persons (excluding widows, children, and dependents) in receipt of pensions at August 1st, 1920, was 1,117,000, and at Feb. 1st, 1921, 1,060,000; and the respective annual cost thereof £61,598,000 and £60,484,000 approximately. The annual expenditure incurred in respect of medical boards is £1,712,000, the cost in salaries and fees to medical officers being £994,000. There were 565 whole-time medical officers employed on August 1st, 19.0 (215 being engaged at institutions) and 592 employed on Feb. 1st, 1921, of whom 267 were engaged at institutions. The number of disabled men who were in receipt of pensions at August 1st, 1920, and whose pensions have ceased for the reasons stated is 103,000. The number of 20 and 30 per cent. pensions in payment at Feb. 1st, 1921, is 300.000 and 245,000 respectively. With regard to the last part of the question, my honourable and gallant friend will no doubt recollect the agitation in Parliament and elsewhere, which led to the formation of three-men boards for national service.

Health of the Troops in Cologne.

Lieutenant-Colonel BUCKLEY asked the Secretary of State for War whether his attention had been called to grave allegations concerning the Army of the Rhine which had been made by the Rev. W. Talbot Hindley, a chaplain of the Territorial Force; and, in particular, whether there was anything to justify the statements that the conditions of life in Cologne made a death-trap for our soldiers; that 95 per cent. of one unit had been through hospital; and that there was a cemetery which was largely filled with suicides and victims of venereal disease.—Sir L. WORTHINGTON-EVANS replied: My attention has been called to the allegations in question, and the Army Council are in communication with the reverend gentleman concerning them. There is no justification whatever for the statements attributed to him. During the period from Jan. 1st, 1920, to Jan. 31st, 1921, the monthly average of admissions for venereal disease was 1·4 per cent. of the total strength; there were 85 deaths from all causes, but none from venereal disease, and only 5 from wounds self-inflicted.

The Services.

ARMY MEDICAL SERVICE.

Col. L. P. More is placed on half pay.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. M. P. Corkery is placed on retired pay on account of ill-health contracted on active service.

Major T. E. Harty relinquishes the acting rank of Lieutenant-Colonel.

Major C. Kelly is placed on the half-pay list on account of ill-health.

Major J. B. Clarke retires on retired pay.

Temp. Major J. H. Spencer to be Captain and to retain the temporary rank of Major.

ARMY DENTAL CORPS.

Temp. Major J. P. Helliwell, from Special List, to be Lieutenant-Colonel and to be Inspector of Dental Services.

SPECIAL RESERVE OF OFFICERS.

Capt. R. T. C. Robertson to be Major.

Capt. P. Walsh relinquishes the acting rank of Major.

Capt. E. T. H. Lea relinquishes his commission on appointment to the R.A.M.C. (T.F.).

TERRITORIAL FORCE.

Capts. J. L. Menzies and E. T. H. Lea to be Majors.

Capt. B. E. A. Batt (late R.A.M.C.) and Lieut. H. G. Kilner (from 5th Battalion Suffolk Regiment) to be Captains.

Capt. L. H. Taylor (late R.A.M.C.) to be Lieutenant, and to relinquish the rank of Captain.

Capt. L. D. B. Cogan resigns his commission and is granted the rank of Lieutenant-Colonel.

INDIAN MEDICAL SERVICE.

Temp. Lieut. D. T. P. Gay to be temporary Captain.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on March 5th the following were appointed members of the board of electors to the Sir William Dunn Professorship of Biochemistry:—

Professor Sir W. J. Pope, Mr. F. F. Blackman, St. John's; Professor T. B. Wood, Mr. W. B. Hardy, Caius; Professor W. M. Bayliss, Professor J. N. Langley, Professor J. S. Gardiner, and Professor C. J. Martin.

The following degrees were conferred:—

M.D.—E. J. Bradley, Jesus.
M.B. and B.Ch.—A. G. Shurlock, Jesus; N. W. Jenkin, Christ's; H. B. Yates, Downing.
M.B.—E. E. Llewellyn, Christ's.
B.Ch.—F. N. Sidebotham, Clare.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held in February the following candidates passed in the subjects indicated:—

Surgery.—W. A. Bryce (Sects. I. and II.), Birmingham; A. R. Crane (Sect. I.), London Hosp.; Z. Khaled (Sect. II.), Cairo; G. G. Rigby (Sect. I.), Manchester; B. W. Roffey (Sects. I. and II.), St. Mary's Hosp.
Medicine.—W. A. Bryce (Sects. I. and II.), Birmingham; O. G. Fisk (Sects. I. and II.), Cambridge and London Hosp.; M. Foley (Sect. I.), Charing Cross Hosp.; B. W. Roffey (Sect. I.), St. Mary's Hosp.; H. W. Swann (Sects. I. and II.), St. Mary's Hosp.; J. Solomonoff (Sect. II.), London Hosp.; M. Tcherny (Sects. I. and II.), Zurich.
Forensic Medicine.—W. A. Bryce, Birmingham; E. C. T. Clouston, London Hosp.; O. G. Fisk, Cambridge and London Hosp.; M. Foley, Charing Cross Hosp.
Midwifery.—A. G. L. Brown, Westminster Hosp.; R. E. Williams, Guy's Hosp.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: Z. Khaled and H. W. Swann.

UNIVERSITY OF LONDON.—The ceremony of Presentation Day will be held in the Royal Albert Hall on Thursday, May 5th.

THE Croonian lecture will be delivered at the Royal Society on May 5th by Dr. Henry Head, F.R.S., on Release of Function in the Nervous System.

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN: APPEAL FUND.—An "At Home" was given by Lady Emmott, J.P., Mrs. Anstruther, and Dr. Christine Murrell on March 3rd, when the laboratories and lecture theatres were open to the guests, and short talks on the past, present, and future of the school and hospital were given by Lady Barrett, Dr. Louisa Garrett Anderson, Professor Winifred Cullis, and Dr. Dorothy Hare. An appeal for £500,000 is being made by this school, where an obstetric and gynæcological unit, directed by Professor Louisa McIlroy, has just been initiated.

ROYAL INSTITUTION.—Among the lectures to be given at the Royal Institution after Easter are four lectures by Professor A. Keith on Darwin's Theory of Man's Origin. Dr. C. S. Myers will give three lectures on Psychological Studies, one on Localisation of Sound, and two on Appreciation of Music. Dr. H. H. Dale will lecture on Poisons and Antidotes, and Mr. E. C. C. Baly on Chemical Reaction. The Friday evening meetings will be resumed on April 8th, when Dr. R. H. A. Plimmer will deliver a discourse on Quality of Protein in Nutrition. Discourses will be given in the course of the session by Sir James Walker, Professor W. Bateson, Professor E. H. Starling, Dr. Leonard Huxley, and others.

MEDICAL SOCIETY OF LONDON.—At the next meeting on Monday, March 14th, at 8.30 P.M., a discussion on Non-operative Treatment of Surgical Tuberculosis will be opened by Sir Henry Gauvain, followed by Sir A. Bowlby, Mr. T. H. Kellock, Dr. W. T. Gordon Pugh, and Mr. W. H. Trethowan.

Anniversary Dinner.—The 148th anniversary dinner of the Medical Society of London was held at the Wharncliffe Rooms, London, on Tuesday, March 8th, Sir William Hale-White presiding. After the usual loyal toasts the chairman gave an entertaining outline of the movements in the eighteenth century which gave rise to a number of medical societies, the Medical Society of London among them. As one who had stood out against compelling students to go to bad lectures he was a convinced supporter of the oral method in teaching and of the value of free discussion. Sir Anthony Bowlby proposed "The Imperial Forces," giving striking instances of what a medical service could do for an army, and what might be the results of its failure; Sir Robert Hill and Air-Commodore Fell replied. Sir John Bland-Sutton wittily proposed "The Visitors," Lord Justice Atkin and Dr. Russell Wells replying. Sir D'Arcy Power paid graceful tribute to the President. The occasion was one of good fellowship and happy reunion.

Chelsea Clinical Society.—The annual debate will be held on April 19th, instead of as previously arranged.

King Edward's Hospital Fund for London.—Hospitals situated in the County of London or within nine miles of Charing Cross and desiring to participate in the grants made by this fund for the year 1921 should make application before March 31st to the honorary secretaries at 7, Walbrook, London, E.C.4. Applications will also be considered from convalescent homes within the above boundaries or which, being situated outside, take a large *proportion of patients from London ; also from sanatoriums* for consumption which take patients from London or which are prepared to place beds at the disposal of the fund for the use of patients from London hospitals.

Edinburgh Undergraduates in Paris.—A class composed of 18 men and 17 women students of the University of Edinburgh left England on March 5th for a four weeks' course of practical midwifery. The distinguished French teachers who will give lectures and demonstrations include Professor A. Couvelaire, Professor P. Bar, Professor M. Chauffard, Professor J. L. Faure, Dr. Legris, Dr. Vaquez, Dr. Bouffe de St. Blaise, Dr. J. Funck-Brentano, Dr. Latulle and Dr. Besançon, Dr. Margan and Dr. F. Widal. The students will work at the Clinique Tarnier, the Clinique Baudelocque, the Clinique de la Pitié, and will visit laboratories, museums, maternity and infants' hospitals. At the end of the course a certificate will be issued to those who have taken part.

Donations and Bequests.—The late Mr. William Morrice Ledingham, of Aberdeen, has left personal estate of the value of £154,423 5*s.* 3*d.*, the residue of which is to be divided into 17 parts—four parts for the Aberdeen Royal Infirmary; two parts for the Aberdeen Royal Hospital for Sick Children; one part each to the Morningfield Hospital, the Ophthalmic Institute, the Aberdeen Dispensary, Maternity Hospital, and Vaccine Institute, the Aberdeen Nursing Association, the Aberdeen Ladies' Sanitary and Rent Aid Association, Newhills Convalescent Home, the Association for Improving the Condition of the Poor, Spurgeon's Home, Dr. Barnardo's Homes, Aberdeen Asylum for the Blind, and the Ophthalmic Hospital.—The residue of the property of the late Colonel Francis John Ryder, which will exceed £25,000, is to be divided between the Leeds Infirmary, London Hospital, Guy's Hospital, St. Thomas's Hospital, St. Bartholomew's Hospital, Charing Cross Hospital, and the University of Edinburgh.—The late Mr. Thomas Burnett Middleton, of Watson-street, Aberdeen, has left, free of legacy duty, £50 to the Aberdeen Royal Infirmary and £50 to the Royal Aberdeen Hospital for Sick Children.—The late Mrs. Eliza Bruce, or Wallace, Gowanlea, Ellon, leaves, free of legacy duty, to the Aberdeen Royal Infirmary £50.—As the result of a concert given by the staff of Messrs. John Falconer and Co., drapers, Union-street, Aberdeen, a sum of over £200 was handed over to the Sir James Taggart Fund for the Royal Aberdeen Hospital for Sick Children.

Liverpool Royal Infirmary. — The annual meeting of governors was held on March 4th, when Dr. Richard Caton, the President, occupied the chair, and was supported by the Lord Mayor and the Vice-Chancellor of the University. Mr. Holford Harrison, the honorary treasurer, in submitting his report stated that during 1920 there had been 4193 in-patients and 27,110 out-patients, the average daily attendance of the latter being 528. There had been a great increase in the attendances at the massage department. The number of pensioners in respect of whom payments were received from Government had decreased, but civilians had come forward in large numbers for massage treatment, and the necessary increase in the staff of masseuses had added to the expenditure of the hospital without any commensurate financial return. There was also a greater demand for treatment in the X ray department, and to bring the equipment up to present-day requirements a special expenditure of £1000 for new apparatus had been sanctioned. The total expenditure for the year amounted to £55,337, an excess of £6906 over the receipts. The balance-sheet would have shown a greater deficiency had it not been for a special contribution of £9000 from the Lord Mayor's Appeal Fund and receipts of £2802 from legacies. The financial position was a source of serious anxiety, and if the hospital was to continue its usefulness greatly increased assistance was necessary. Owing to the increased cost of maintenance the committee had found it necessary to raise the charge to "outside radius" in-patients to 20*s.* per week, and the desirability of making what contributions they could to the cost of their maintenance was being systematically laid before in-patients. The need for a new nursing home was becoming ore and more urgent. Of the out-patients, 26 per cent. re insured persons making weekly contributions to the tional Health Insurance scheme, from which the infirmary did not receive a penny. Dr. Caton, in moving the adoption of the report, said that the old class of generous subscribers to the voluntary hospitals were at present labouring under the burden of heavy taxation and could not be expected materially to increase their subscriptions. He hoped that the day was far distant when the hospitals would have to rely entirely on the State or the municipalities for their support, as such a change would be followed by diminished efficiency and probably trebled expenditure. If the infirmary was obliged to accept State or municipal aid he trusted it would be only a small defined proportion of their voluntary funds, so that voluntary support and the present method of government could be continued. Not a farthing of the National Health Insurance Fund was paid to the hospital, though many insured persons were treated there. This grievance should be pressed on the notice of the Government; the hospital might hope to receive £3000 or £4000 annually from this source. Voluntary contributions from in-patients might yield from £4000 to £5000. The Lord Mayor, in seconding the adoption of the report, agreed with the principle of asking patients to contribute towards their maintenance according to their ability. Mr. G. H. Melby was elected president for the ensuing year, and Mr. Holford Harrison was re-elected honorary treasurer. The report showed that the ordinary income was £2948 above that of the previous year—every source of income having shown an increase except the receipts in respect of ex-Service men. But, owing to the increased cost of commodities and the expenditure on long delayed works of cleaning and repair, the ordinary expenditure was £7030 above that of last year. The total ordinary income was £36,983, and the total ordinary expenditure was £24,361. A grant of £7500 was received from the Lord Mayor's Special Appeal Fund, but the amount from legacies was only £1807 as compared with £14,335 in 1919. There had been an increase in payments by, or in respect of, patients of £4652. Part of this very satisfactory improvement was due to the appointment of an almoner.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

Alexander, R. C., M.B. Edin., F.R.C.S.E., has been appointed Visiting Surgeon to Dundee Royal Infirmary.

Gerrard, Dora W., M.B., Ch.B. Edin., Junior House Surgeon at the Children's Hospital, Sunderland.

Ivens, Frances, M.B., M.S. Lond., Honorary Surgeon to the Liverpool Maternity Hospital.

Lyster, R. A., M.D., B.Ch. Birm., D.P.H., a Member of the Central Midwives Board.

Middleton, E. L., M.D. Edin., D.P.H., Medical Inspector of Factories and Workshops.

Rivett, L. C., M.C. Cantab., F.R.C.S. Eng., Obstetric Surgeon to Out-Patients at Queen Charlotte's Hospital.

Stannus, H. S., M.D. Lond., M.R.C.P. Lond., Medical Adviser to the Board of Inland Revenue and Physician to Out-patients, French Hospital, London.

Tanner, W. E., M.S. Lond., F.R.C.S. Eng., Surgeon to Out-patients, The Evelina Hospital for Children, Southwark.

Certifying Surgeons under the Factory and Workshops Acts: **Laurie, A. M.**, L.R.C.P. & S. Edin. (Bridge of Weir and Kilmacolm); **Mackenzie, J. J. R.**, M.B., Ch.B. Edin. (King's Cliffe); **Sugden, F.**, M.B., Ch.B. Vict. (Wansford).

Medical Referees under the Workmen's Compensation Act, 1906: **Edington, G. H.**, M.D. Glasg., and **Rutherford, H.**, M.B., C.M., for the Sheriffdom of Lanark.

Vacancies.

For further information refer to the advertisement columns.

Birmingham and Midland Homœopathic Hospital.—Res. H.S. £125.

Birmingham General Dispensary.—Res. M.O. £400.

Birmingham, Queen's Hospital.—H.P.'s, H.S.'s, Obstet. and Ophth. H.S., and Cas. H.S. £90 each.

Birmingham, St. Chad's Hospital.—Res. M.O. £100.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. £150.

Swansea County Borough.—Asst. M.O. £500.
Tiverton Hospital.—H.S. £100.
Tunbridge Wells General Hospital.—H.S. £160.
West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. £50. *Also Asst. Anæsth.*
West Riding County Council.—Asst. M.O. at Cardigan Sanatorium, Carr Gate, near Wakefield. £500.
Wolverhampton and Staffordshire General Hospital.—Hon. Specialist.
York Retreat.—Med. Supt. £800–£1000.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Horsforth, Clevedon, and Frome.

Births, Marriages, and Deaths.

BIRTHS.

ABRAHAM.—On March 4th, at 59, Cambridge-terrace, W.2, Lilian Angela (née Francis), wife of J. Johnston Abraham, C.B.E., D.S.O., F.R.C.S., of a daughter (Joan Lilian).

ASH.—On March 6th, the wife of H. Arnold Ash, M.R.C.S., L.R.C.P., of 59, Madrid-road, Barnes, of a son.

COURTNEY.—*On March 6th, the wife of J. M. Courtney, M.R.C.S., L.R.C.P., of Bocking*, Braintree, Essex, of a daughter.

MILLIGAN.—On Feb. 19th, at Woodlands-road, Ansdell, Lytham, Lancs, the wife of W. E. Milligan, M.B., B.S., of a son.

ROUTH.—On March 6th, at Norwich, *the wife of Captain L. M.* Routh, M.D., R.A.M.C., Military Hospital, Norwich, of a son.

MARRIAGES.

HUGHES—POLLOCK.—On March 1st, *at All Saints' Church, Marseilles*, Cecil H. M. Hughes, M.B., to Anne Athol, widow of W. Rivers Pollock, M.D., F.R.C.P.

WOOLRICH—BALLARD.—On March 3rd, at All Saints' Parish Church, Sanderstead, Surrey, William Grant Woolrich, M.A., M.R.C.S., to Lorna, eldest daughter of Mr. and Mrs. M. J. Ballard, Sanderstead.

DEATHS.

ARMSTRONG.—On Feb. 24th, at Quetta, of enteric fever, Captain (temp. Major) Edward Randolph Armstrong, M.D., D.P.H., D.T.M., I.M.S., D.A.D.M.S. (Sanitary), Quetta Division, in his 36th year.

DUKE.—On *March 6th, at Eastbourne, Edgar Duke, M.D., M.R.C.S.* (late Captain, R.A.M.C.), of Hove.

FRY.—On March 4th, at his residence, Tonbridge-road, Maidstone, Kent, John William Fry, M.R.C.S., L.S.A., in his 90th year.

GATLEY.—On Feb. 28th, at Mill Vale House, Bratton, Westbury, Charles Alexander Robertson Gatley, M.R.C.S., L.R.C.P., aged 31 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, March 14th.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.

Discussion:

On "The Eradication of Tuberculosis in Men and Animals." To be opened by Sir John McFadyean, followed by Sir Clifford Allbutt, Dr. Arthur Latham, Professor Hobday, Dr. A. C. Inman, Mr. Cyril Nitch, Sir Sims Woodhead, and others.

Tuesday, March 15th.

GENERAL MEETING OF FELLOWS: at 5 P.M.

Ballot for Election to the Fellowship. (Names already circulated.)

MEETINGS OF SECTIONS.

Friday, March 11th.

CLINICAL SECTION
SECTION OF MEDICINE } at 5.30 P.M. (Cases at 5 P.M.)
SECTION OF SURGERY

Cases: The following will be shown by—

Sir Thomas Horder: Diffuse Sclerodermia.

Dr. Maurice Cassidy: Specimens from Neoplasm of Lung.

Mr. Paul Bernard Roth: Arterio-venous Aneurysm.

Mr. Kilner: Three Cases illustrating Plastic Surgery of the Face.

Adjourned Discussion:

On "The Medical and Surgical Treatment of Graves's Disease" will be continued by Mr. Joll, Dr. Leonard Williams, Dr. C. M. Wilson, Dr. Thorne Thorne, Mr. Dunhill, and Dr. Hector Mackenzie.

SECTION OF NEUROLOGY
SECTION OF OPHTHALMOLOGY } at 8.30 P.M.

Adjourned Discussion: On "Ocular Palsies."

Monday, March 14th.

WAR SECTION: at 5.30 P.M.

Paper: Colonel H. E. R. James: The Best Form of Instruction for Medical Students to Fit them to take their Part in Case of National Emergency.

Tuesday, March 15th.

SECTION OF THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.

Paper:

Mr. Paul Bernard Roth: The Uses of Heliotherapy (illustrated by two cinematograph films and lantern slides).

Members of other Sections who are interested are cordially invited to attend the above meeting.

SECTION OF PATHOLOGY: at 8.30 P.M.

Communications:

Sir Lenthal Cheatle: Parenchymatous Inflammation of the Breast.

Dr. J. A. Murray and Dr. W. H. Woglom: Experimental Tar Cancer.

Dr. A. J. Eagleton: The Standardisation of Antipneumococcal Serum.

Dr. Nathan Raw: Attenuated Tubercle Bacilli.

Wednesday, March 16th.

SECTION OF HISTORY OF MEDICINE: at 5 P.M.

Papers:

Professsor G. Elliot Smith: Ancient Egyptian Pathology and Medicine.

Mr. Geoffrey Keynes: The Unpublished Letters of Sir Thomas Browne.

Mr. Marshall Montgomery: The Identity of "Cursed Hebenon" in Shakespeare's *Hamlet* with Lignum Vitæ.

SECTION OF STUDY OF DISEASE IN CHILDREN: at 8.30 P.M.

Adjourned Discussion:

On "The Diagnosis and Treatment of Congenital Syphilis," to be reopened by Dr. Morley Fletcher, and continued by Mr. John Adams, Dr. Jewesbury, Mr. McDonagh, Mr. Neame, Dr. Pitts, and others.

Thursday, March 17th.

SECTION OF DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)

Communication:

Mr. T. C. Benians: The Presence of Catalytic Enzymes as an Aid to Diagnosis of Hair Infections.

Cases: The following will be shown by—

Dr. Knowsley Sibley: Monilethrix.

Dr. Hannay: Two Cases of Pityriasis Rubra Pilaris.

Friday, March 18th.

SECTION OF OTOLOGY: at 5 P.M.

Demonstration of Pathological Specimens by Dr. Albert Gray.

Paper: Mr. Jefferson Faulder and Mr. Colledge: Ears under Modern War Conditions.

Cases will be shown by—

Mr. Mollison, Mr. Cleminson, Mr. Colledge, and others.

SECTION OF ELECTRO-THERAPEUTICS: at 8.30 P.M.

Mackenzie-Davidson Memorial Lecture:

Professor W. D. Halliburton: Physiological Advance—the Importance of the Infinitely Little.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 14th.—8.30 P.M., Discussion on Non-operative Treatment of Surgical Tuberculosis, to be opened by Sir Henry Gauvain, followed by Sir A. Bowlby, Mr. T. H. Kellock, Dr. W. T. G. Pugh, and Mr. W. H. Trethowan.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

MONDAY, March 14th.—8 P.M., Cantor Lecture:—Major G. W. C. Kaye: X Rays and their Industrial Applications. (II.)

PVEIAN SOCIETY OF LONDON, at the Town Hall, Paddington en, W.

THURSDAY, March 17th.—8.30 P.M., Harveian Lecture:—Dr. L. Williams: The Thymus Gland in Every-day Life.

LONDON DERMATOLOGICAL SOCIETY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, March 15th.—4.30 P.M., Pathological Specimens. Cases sent for Consultation. Clinical Cases will be shown by Dr. J. L. Bunch, Dr. W. Griffith, Dr. W. K. Sibley, Dr. L. G. Pearson, Dr. A. C. Ribello, Dr. M. G. Hannay, and Dr. D Vinrace. Paper:—Dr. R. Craik: The Ringworms—some Observations on their Mycology.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at the Royal Army Medical College, Grosvenor-road, S.W.

FRIDAY, March 18th.—8.15 P.M., Laboratory Meeting. Demonstrations:—Col. P. S. Lelean: Models of Some Sanitary Devices for the Tropics. Lt.-Col. J. C. Kennedy: The Pathological Histology of Tropical Sore. Lt.-Col. H. Marrian Perry: A Helminthic Infection in Relation to Bacterial Invasion of Tissues. Major F. N. Coppinger: Preliminary Work in Connexion with Detoxicated Dysentery Vaccines. Dr. J. G. Thomson and Dr. A. Robertson: Association of Charcot-Leyden Crystals with *Entamœba Histolytica*. Dr. H. St. J. Brooks: *Leptospira Icteroides* and *Leptospira Icterohæmorrhagiæ*. Dr. P. Manson-Bahr: *Bacillus Coli* Infections of Tissues. Miss E. M. Baxter and Dr. A. J. Eagleton: Can Syringes be Sterilised by Means of Oil? Dr. A. Castellani and Dr. F. E. Taylor: Identification of Sugars and Other Carbohydrates by a Mycological Method. Mr. Cecil A. Hoare: Demonstration of Trypanosomiasis of British Sheep. Lt.-Col. S. P. James: A Case of Leprosy. And others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, March 14th.—12.15 P.M, Dr. Burnford: Pathological Demonstration. 2 P.M., Dr. S. Pinchin: Medical Out-patients. Mr. B. Harman: Eye Department. 5 P.M., Lecture:—Dr. G. Stewart: Syringomyelia.

TUESDAY.—10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Mr. T. Gray: Surgical Out-patients. 2.30 P.M., Dr. Pritchard: Demonstration of Cases (Surgical Wards). 5 P.M., Lecture:—Dr. Pernet: Acquired Syphilis in Infancy and Childhood, with Remarks on Late Tertiary Congenital Syphilitic Manifestations.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Addison: Operations. Dr. Morton: X Ray Department. 5 P.M., Lecture:—Mr. Gibb: Glaucoma.

THURSDAY.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 2 P.M., Mr. Baldwin: Orthopædic Department. Mr. D. Armour: Operations. 5 P.M., Special Lecture:—Dr. B. Ball: Nasal Suppuration (with lantern slides) (open to all medical practitioners).

FRIDAY.—10 A.M., Dr. G. Stewart: Neurological Demonstration. Mr. D. Buxton: Dental Department. 2 P.M., Dr. Pernet: Skin Department. 5 P.M., Lecture:—Mr. Steadman: Dental Sepsis in Relation to the Alimentary Tract.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, March 14th.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Saunders: Friedreich's Ataxia.

TUESDAY, March 15th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Risien Russell: Syphilis of the Nervous System. (II.)

THURSDAY, March 17th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Dr. Saunders: Occupation Neuroses.

FRIDAY, March 18th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Hinds-Howell: Disseminated Sclerosis.

Fee for Post-Graduate Course £7 7s. C. M. HINDS HOWELL, Dean.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

FRIDAY, March 18th.—3 P.M., Sir James Kingston Fowler: The Treatment of Tuberculosis.

KING'S COLLEGE (DEPARTMENT OF SCIENCE), Strand.

Nine Lectures on Problems of Modern Science.

WEDNESDAY, March 16th.—5.15 P.M., Lecture (IX.):—Prof. E. Barclay-Smith: Anatomy.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 17th.—4 P.M., Lecture:—Dr. Hutchison: Disorders of the Liver.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

MONDAY, March 14th.—5.30 P.M., Post-Graduate Lecture:—Dr. S. Goodall: Practical Points in Treatment.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

TUESDAY, March 15th.—3 P.M., Lecture:—Prof. A. Keith: *Darwin's Theory of Man's Origin.*

THURSDAY.—3 P.M., Dr. G. C. Simpson: Meteorology of the Antarctic.

SATURDAY.—3 P.M., Lecture (III.): Sir Ernest Rutherford: Electricity and Matter.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, March 15th.—4.30 P.M., Lecture:—Mr. H. H. Rayner: Surgical Disorders of Infancy and Early Childhood (contd.)

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, March 17th.—4.30 P.M., Dr. White: Diseases of the Eye. (At Salford Royal Hospital.)

Notes, Short Comments, and Answers to Correspondents.

COLONIAL HEALTH REPORTS.

Somaliland.—In a report on the Protectorate for the year 1919-20, signed by Mr. D. J. Jardine, Secretary to the Administration, it is stated that the average number of Europeans resident was 36, and the total of them on the sick list was 30, of whom 4 were invalided to England. During 1919 2064 patients were admitted to hospitals, as compared with 2421 in 1918 and 1039 in 1917. In 1918 the numbers were raised by an epidemic of influenza, and in the year under review there was a small-pox epidemic. The number of out-patients was 19,916, which differs little from the figures for previous years. There was a further decrease in the number of malarial cases, 500 being reported as against 558 in 1918, and 1 death from malaria as compared with 13 in 1918. Relapsing fever, on the other hand, is on the increase. The disease occurs at Hargeisa, where the *Ornithodorus moubata* tick is found. In the early stages of the disease intravenous injections of a salvarsan preparation, such as neo-kharsivan, have proved very successful. There were 132 cases of scurvy, as compared with 47 in the previous year. Most of the cases were slight and occurred amongst the Indian troops owing to the difficulty of obtaining a regular supply of fresh limes and fruit from abroad. There were no deaths from this disease. There were 5260 cases of ulcer treated during the year as compared with 4614 cases for 1918. The majority of cases appear to be the ordinary tropical ulcer, or "Aden ulcer," as it is sometimes called, which is very common on the Red Sea littoral. Small-pox was present in epidemic form during the whole of 1919. The first recorded case came from Abyssinia to Hargeisa, whence, owing to the nomadic habits of the people, the disease spread throughout the country. 662 cases were admitted to the isolation camps, where there were 296 deaths. The outbreak was not severe; but there must have been many cases and deaths in the interior which never came to the notice of the medical department. Some villages, indeed, where the disease was rampant, were abandoned by the inhabitants. There were 104 cases of chicken-pox, as compared with 20 cases in the previous year. The influenza epidemic of 1918 did not recur in 1919; there were only 69 cases of this disease, mostly at the coast, and 4 deaths. There were 59 cases of dysentery, some of which were definitely amœbic and appear to have been brought by troops from East Africa. Venereal diseases were still on the increase, 262 cases of syphilis and 516 cases of gonorrhœa being recorded, as against 143 and 339 respectively in the previous year. Tuberculosis, chiefly of the lungs, is also steadily increasing, 300 cases being recorded during the year. The total rainfall in Berbera in 1919 was 2·31 inches, as against 1·93 in 1918. In the interior the rainfall is considerably more than this, but up to the present it has not been practicable to keep records except in Berbera. The highest shade temperature recorded at that station was 116° F. in August, and the lowest 63° in January.

Swaziland.—A census taken in 1911 showed that the total population was 99,959, comprising 1083 Europeans, 143 coloured, and 98,733 natives. The European population is now about 1800. The births amongst Europeans in 1919 numbered 50, the deaths 25, and the marriages 10. The births and deaths of natives are not registered. The general health of the territory during 1919-20 was fairly good, and no epidemic of any importance occurred. During and for some months after the rainy season malarial fever was above the normal, especially in the low-lying parts. In some cases it was associated with influenza, but deaths were confined to natives out of touch with medical attendance. Leprosy has not increased, but the necessity for segregation of the few existing cases is receiving attention. The natives are still loth to report cases of venereal disease, but the coöperation of the police in bringing cases to light has been of great assistance, and many cases have been treated with satisfactory results. The average rainfall in 1919, as recorded at 17 stations throughout the territory, was 38·42 inches—considerably below the normal. Both rainfall and temperature vary considerably with the altitude of the station. At Mbabane, which lies at an altitude of 4000 feet, the highest screen temperature recorded was 95·3° and the lowest 35°. At Croydon, in the low veldt, the maximum was 106° and the minimum 35·5°. The only Government hospital in the territory is at Mbabane. It contains one European and two native wards. There were 123 admissions during the year, and nearly 3670 out-patients were treated.

Bechuanaland.—Mr. J. Ellenberger, Government Secretary, reports that the health conditions throughout the Protectorate for the year ended March 31st, 1920, were of average incidence and not remarkable for any feature of special prevalence. 2300 cases received hospital treatment. Of these, 44 were indoor. Of the outdoor cases, the prevailing disease was malaria, or conditions directly or indirectly due to it; the remainder, general, medical, and surgical affections. Several outbreaks of malaria were reported from the remote and outlying districts; and at some of these places there was a high death-rate from intercurrent diseases, such as pneumonia. There has been no recurrence of epidemic influenza anywhere throughout the territory, and there has been a complete absence of outbreaks or isolated cases and other general epidemic diseases.

Uganda.—In the latest official report on this Protectorate the following remarks appear under the heading "Climate and Meteorology": Uganda cannot be considered healthy, but its recent notoriety due to the ravages of sleeping sickness can now be safely neglected; it is neither a "white man's country" nor the "white man's grave." For a family man the country possesses distinct disadvantages. European children as a rule thrive well in infancy, but considerable risk is attached to bringing them out when they are over 2 or 3 years old, as they are liable to attacks of malaria and the resultant anæmia. The health of adults depends mainly on their mode of life, and with care constitutional health should not be impaired irremediably, but if physical fitness is maintained the altitude and proximity to the equator combine to produce nervous strain after prolonged residence. A holiday in a temperate climate is desirable at least every two or three years. Outdoor manual labour is dangerous for Europeans, and on plantations a manager's or owner's duties are for the most part supervisory. The mean maximum temperature for most districts averages 80°, and the mean minimum 60°. On the Ruwenzori range there is extreme cold with perpetual snow, and it is also cold on the higher slopes of Mount Elgon. In the Nile Valley, near Lake Albert, on the other hand, the mean maximum temperature is 90° and the mean minimum 74°. The favourite localities for European plantations are the Buganda Province, the Toro district of the Western Province, and the Bunyon district of the Northern Province. There are a few estates in Busoga (Eastern Province), but this area is not so popular. Statistics taken at Entebbe, the seat of the Government, give the following results: Average rainfall for the last 19 years, 58·64 inches; average temperature for the last 15 years, maximum 78·5°, minimum 62·8°; mean daily sunshine, 5 hours 36 minutes. Two main rainy periods are anticipated annually. The first, the "long" rains, usually begin in March and may continue through June. The second, or "short," rains begin in September and extend through October and occasionally November. Much of the rain falls during the night or early morning and seldom continues throughout the day.

Zanzibar.—The population of this Protectorate according to the last census was 196,733. The birth-rate in 1919 was 18·5 per 1000 of population, as against 19·4 in 1918. The report omits to give the death-rate, but states that the islands of Zanzibar and Pemba were free from any severe epidemic of disease during the year, except a slight recurrence of influenza in October, and the health of the community has been fair. There were 37 deaths from tuberculosis, 21 from malaria, 14 from dysentery, 2 from small-pox, and 1 from cerebro-spinal fever.

THE TEMPERATURE FACTOR IN THE ONSET OF PUBERTY.

IT is generally accepted that the onset of puberty begins earlier in the tropics than in temperate zones, and is correspondingly delayed in the extreme north or south. It is recognised that the period of onset bears a relation to the temperature of the geographical area. At first glance it might appear that in North America the temperature does not play this rôle, for missionaries have recorded many cases of Eskimo women at Point Barrow in Alaska, 300 miles north of the polar region, who have been delivered of their first child at 12, or even at 11 years of age. Vilhjamur Stefansson, in the *Journal of the American Medical Association*, lxxv., 1920, can from his own observations confirm the statement that in Eskimo girls maturity arrives at from 10-13 years. The explanation, however, appears to lie in a consideration of the conditions under which the girls are brought up and live. It appears that the temperature of the interior of their dwelling places is maintained at about 80° to 90° F., even when the external temperature is 40° to 50° below zero. The fur coverings in which the Eskimos envelop their bodies protect them fully against these low temperatures, so that they actually live in a temperature akin to that of [illegible] where early maturity seems to be largely [illegible] on the high temperature. In their dwelling[illegible] —so hot are they—the Eskimos put aside [illegible] coverings, all except a pair of pants, and the [illegible] that even then there is an almost constant outpour of sweat over the body. Possibly the artificial heat, like the sun's heat in tropical climes, greatly modifies the metabolism. Amongst the Eskimos the heat acts directly more on the women than the men, because the former live more in their dwellings. Amongst the Doy-Rib and Yellow-Knife Indians maturity of the girls occurs about the same time or later than amongst the white races of Northern Europe. This condition stands in relation with the mode of life of these tribes, living in less heated tents, wearing lighter clothing, and exposed more directly to their cold raw climatic influences.

AN INSULATED VESSEL.

WE have received from the Aladdin Industries, Ltd., 130, Southwark-street, London, S.E.2, a specimen of a "Thermalware" jar, which looks like a useful addition to the equipment of the housekeeper and of the traveller, or indeed wherever it is required to keep food or drink hot or cool. The apparatus consists of an outer aluminium jacket of barrel shape and an inner vessel of silvered glass holding a gallon, the space between the two vessels being filled with a non-conducting material. The mouth of the vessel is 4 inches wide, thus allowing the insertion of the hand for packing the container with solid food or for cleaning purposes. The insulation is effective, the fall in temperature of the contents of the jar not exceeding 7° in an hour. For the sick-room the vessel suggests many possibilities—e.g., the storage of ice for packs, of hot flannels for fomentations, or of blood-warm fluid for transfusion. The apparatus is artistically finished, it is constructed on sound hygienic lines, and risk of breakage is reduced to a minimum.

THE QUEEN'S NURSES AT BRIGHTON.

THE Brighton, Hove, and Preston District Nursing Association, to which the Queen's Nurses are affiliated, has had to reduce its staff owing to the lack of funds, and after 24 years' work the annual report announces:—

> "The chief sources of income—voluntary subscriptions, public health work, patients' payments, and training fees for candidates—do not even cover the salaries of staff, uniform, and board."

Another extract from the report says:—

> "It would appear as if in the future the steady income from voluntary subscriptions will no longer be reliable, and the only way to keep the association solvent will be by organising popular functions and amusements to raise funds."

It cannot be said that the decrease in funds is due to any slackness on the part of the nurses, for 1920 was a record year, the number of cases showing an increase of 325 over 1919, the patients nursed being 2406, and the visits paid 80,792. The balance-sheet demonstrates that there has not been a corresponding response on the part of the general public, and the Queen's Nurses will thus be unable to form an important unit in the provident scheme now being organised in Brighton and Hove. A tribute to the work of the Queen's Nurses was paid at the recent annual meeting by Dr. Duncan Forbes, M.O.H., Brighton, who stated that whereas 30 per cent. of the cases admitted to the Blind School owed blindness to inflammation of the eyes just after birth, since the nursing had been undertaken by the Queen's Nurses no further recruits from that cause had been under treatment at the institution. Earnest appeals were made by several speakers for more financial support.

INDUSTRIAL RESEARCH ASSOCIATIONS.

BELOW is a list of research associations which have been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research, and have received licences from the Board of Trade:—

British Boot, Shoe and Allied Trades Research Association, Technical School, Abington-square, Northampton. Secretary: Mr. John Blakeman, M.A., M.Sc.

British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester. Secretary: Miss B. Thomas.

British Empire Sugar Research Association, 3/5, Old Queen-street, S.W. 1. Acting Honorary Secretary: Mr. H. T. Pooley.

British Iron Manufacturers' Research Association, Atlantic Chambers, Brazennose-street, Manchester. Secretary: Mr. H. S. Knowles.

Research Association of British Motor and Allied Manufacturers, 15, Bolton-road, Chiswick, London, W.4. Director of Research: Mr. H. S. Rowell, O.B.E., A.R.C.Sc., Wh. Sch.

British Photographic Research Association, Sicilian House, Southampton-row, London, W.C. 1. Secretary: Mr. Arthur C. Brookes.

British Portland Cement Research Association, 6, Lloyd's-avenue, London, E.C. 3. Secretary: Mr. S. G. S. Panisset, A.C.G.I., F.C.S.

British Research Association for the Woollen and Worsted Industries, "Torridon," Headingley-lane, Leeds. Secretary: Mr. old Frobisher, B.Sc.

ish Scientific Instrument Research Association, 25, Russell- . W.C. 1. Secretary: Mr. J. W. Williamson, B.Sc.

arch Association of British Rubber and Tyre Manufacturers, Messrs. W. B. Peat and Co., 11, Ironmonger-lane, E.C. 2.

Linen Industry Research Association, "Glenmore House," Lambeg, Belfast. Secretary: Miss M. Burton.

Glass Research Association, 50, Bedford-square, W.C. 2. Secretary: Mr. E. Quine, B.Sc.

British Association of Research for Cocoa, Chocolate, Sugar Confectionery, and Jam Trades, 9, Queen-street Place, E.C. 4. Secretary: Mr. R. M. Leonard.

British Non-Ferrous Metals Research Association, Athenæum Chambers, 71, Temple-row, Birmingham. Secretary: Mr. E. A. Smith, A.R.S.M., M.Inst.M.M.

British Refractories Research Association, 14, Great George-street, S.W. 1. Secretary: Mr. R. C. Rann.

Scottish Shale Oil Scientific and Industrial Research Association, 135, Buchanan-street, Glasgow. Secretary: Mr. H. R. J. Conacher.

British Leather Trades Research Association, 26, Thomas-street, S.E. 1. Secretary: Miss M. A. Stevens.

British Launderers' Research Association, 62-5, Bank Chambers, 329, High Holborn, W.C. 2. Secretary: Mr. J. J. Stark.

British Electrical and Allied Industries Research Association, 19, Tothill-street, Westminster, S.W. 1. Director of Research: Mr. E. B. Wedmore.

British Silk Research Association, The Silk Association of Great Britain and Ireland, Incorporated, Kingsway House, W.C. Secretary: Mr. A. B. Ball.

British Motor Cycle and Cycle Car Research Association, "The Towers," Warwick-road, Coventry. General Manager: Mr. H. R. Watling.

British Cutlery Research Association, P.O., Box 49, Sheffield. Secretary: Mr. J. M. Denton.

British Music Industries Research Association, Northern Polytechnic Institute, Holloway, N. 7. Director of Research: Dr. R. S. Clay.

There are other research associations approved by the Department not yet licensed in which schemes for the establishment of research associations have reached an advanced state of development, and yet others only in the proposal stage, or engaged in the preliminary consideration of schemes for forming research associations.

BELGIUM AND MEDICAL RECIPROCITY.

THE abandonment of reciprocity in medical practice between this country and Belgium, mentioned in a leading article in THE LANCET of Feb. 26th, is the subject of a letter in a recent issue of *Le Scalpel* from Dr. Clément Philippe, the President of the Belgian Society of Medicine in England. Our colleague recalls the formation of this society on Nov. 15th, 1914, "during the first days of the exodus." He recounts the rising prosperity of this society, the granting of facilities by the General Medical Council, and his own attempts to secure reciprocity from the Belgian Government in August, 1920. Dr. Philippe has evidently not yet given up hope of ultimate success.

Bees' Wine is apparently an alternative name for the "ginger-beer plant" described by the late Dr. H. Marshall Ward in the Proceedings of the Royal Society for 1891. The so-called plant, which bears superficial resemblance to pearl barley, belongs to the class of symbiotic ferments in which a yeast and bacterium unite, as in such ferments as those used to produce kephir or koumiss. The ginger-beer plant can ferment saccharose, maltose, dextrose, and lævulose, but not lactose, being inferior in this respect to the other ferments named. Mr. E. M. Holmes, F.L.S., gives illustrations of the plant itself and of the symbiotic yeast and bacterium in the *Pharmaceutical Journal* for Jan. 3rd, 1920. The plant appears to be used largely in the North Riding of Yorkshire, to prepare an alcoholic drink, 4 ounces each of sugar and treacle being mixed with half a pint of warm water to which the plant is added, the mixture being kept in a warm place and a teaspoonful of sugar added each day. The plant itself increases, and can be used to prepare fresh batches of liquor. The name "Bees' Wine" may be derived from the apparently purposeful circulation of the fragments of the plant in the fermenting fluid, which are alternately buoyed up to the surface by CO_2 bubbles and sink again after their discharge.

A Clinical Lecture

ON

SUBPHRENIC ABSCESS.

Delivered at Guy's Hospital on Jan. 12th, 1921,

BY C. H. FAGGE, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO GUY'S HOSPITAL.

THE inferior concave surface of the diaphragm is so extensive that in a detailed consideration of the ætiology of abscesses in relation to it we must take into account all the inflammatory conditions of the solid and hollow viscera which lie, even in part, above the level of the infracostal line. Even then we have omitted one organ, the appendix, which formerly, if not now, was regarded as the most common agent in the causation of subphrenic infection. No paper on this subject written during the past 12 years has failed to draw from the store of information which Barnard[1] accumulated from analysis of 76 cases at the London Hospital. From these and others available in 1909 when I lectured[2] on this subject, I was led to the conclusion that about half the cases of subphrenic infection arose from appendicitis. If to-day I suggest that nearly 80 per cent. of such abscesses are due to gastric or duodenal ulceration, we may perhaps venture to argue that the general undertaking of early operation for appendicitis and the adoption of the Fowler position after such operations have been the two chief factors in diminishing the importance of this affection in this relation.

As is obvious from a consideration of the relations of the under surface of the diaphragm, it has been customary to point out that such collections may be intraperitoneal or extraperitoneal. While it has always been admitted that the latter are relatively rare, I should venture to question the existence of a true extraperitoneal abscess arising primarily from an infective process in one of the abdominal viscera, if we accept those which may arise in the retroperitoneal tissues after gunshot wounds, or the rare occurrence of infection of the non-peritoneal surface of the diaphragm by extension from a liver abscess or some other similar condition. Such abscesses, particularly the chronic ones, are so well shut off that their original formation in a loculus of the general peritoneal is easily lost sight of. I can recall only one case on which I have operated in which there was finally any real doubt that it began as an intraperitoneal collection.

CLINICAL TYPES OF ABSCESS.

We have to look for two clinical types of abscess:—

1. The subphrenic abscess, which results from what Moynihan called the subacute or chronic perforation of a hollow viscus, is sometimes acute in onset. Owing to former localising peritonitis, the neighbourhood of the base of an ulcer of the duodenum or stomach is shut off from the general peritoneal cavity and either by direct perforation or extension of infection through the wall of the affected viscus, an abscess forms which is at first limited by the adjacent organs, and as it enlarges points on the abdominal wall. Such an abscess originating from a duodenal ulcer is usually subhepatic, that due to gastric ulceration may point to the right of or to the left of the suspensory ligament, may be perisplenic, or if the perforation has occurred into the lesser sac a retrogastric abscess arises. Similar abscesses may arise from extension of infection from any of the subphrenic organs; thus cases have been recorded from the Mayo Clinic,[3] in which such an abscess resulted from rupture of or operation on the gall-bladder. It is conceivable that some of the subphrenic abscesses originating from diseased appendices —not only of the intraperitoneal variety but those which formerly were described as extraperitoneal—were of a similar pathology and due to the subacute perforation of a hollow viscus. I am inclined to regard the latter of no great practical importance at the present time, for owing to early operation we do not see such cases now.

During the late war perforation of the viscera of the upper abdomen by infected missiles not infrequently led to abscess formation which was usually on the left side owing to the frequency of involvement of the stomach.

Capt. R. was operated on by Captain Owen Richards at a C.C.S. for a gunshot wound of the left epigastrium on Dec. 21st, 1915—a through-and-through wound of the stomach was sutured and the peritoneum drained. He was admitted to Fishmongers Hall Hospital on Feb. 6th, 1916. He vomited up pus on the morning of admission and on the 7th his temperature was 103° F. The left base was dull up to the scapula and a needle withdrew pus; an abscess was drained by excision of part of the tenth left rib. A week later this was explored further and proved to be subphrenic and perisplenic. In March he coughed up two ounces of pus. He still continued to run an irregular temperature and did not pick up. In July he was readmitted to hospital with pyrexia and cough. Much difficulty was experienced in the interpretation of his physical signs and of an area opaque to X rays at the left base, but finally exploration disclosed pus, and an empyema of 10 ounces was drained by resection of part of the ninth rib. His ultimate complete recovery was due to Captain Richards's skill.

2. However, it is not as a primary lesion that the presence of pus under the diaphragm is so often in question in surgical practice, but as a complication in the after-treatment of a patient who has gone through an operation safely for an abdominal lesion, usually an emergency but sometimes an upper abdomen operation of some severity. As I have suggested, these cases differ somewhat in type from those under the first heading; they are more insidious and tax one's diagnostic skill to the utmost. Such a complication in appendix cases is now unusual. If pus forms after operation it usually gravitates into the pelvis, where it is more easily recognised and certainly does less harm than pus in relation to the diaphragm.

Capt. C. was seen with Dr. K. L Bates on Jan. 26th, 1920. He had been ill about a week with pain in the right iliac fossa, which after two or three days diminished and then again increased and passed into the right loin; a lump appeared and pyrexia increased to 101° each night. A large retrocæcal abscess was drained, the appendix, gangrenous terminally, was removed with a large concretion. His temperature was never quite normal and on Feb. 26th rose to 104°. The right loin was tender and the right base dull up to the angle of the scapula. The track of the drainage-tube was opened up and drained into the loin, the chest was explored in three places without result. On March 8th Dr. H. French drew off 42 ounces of clear fluid from the right chest and later Dr. Bates evacuated 30 and 20 ounces, but pyrexia of 100° to 101° continued, and on the 19th there was an area of œdema over the liver. On the 20th I opened up the old wound, evacuated a small collection between the liver and the diaphragm, and drained a right empyema of 20 to 30 ounces by resection of the seventh right rib. Finally, he rewarded Dr. Bates and the nursing staff by getting well.

Recently a trained nurse was sent into my ward with a perforated gastric ulcer, which was closed within five hours; suprapubic drainage was carried out. Her temperature remained up and the pulse was rapid. Impaired resonance at the left base led to exploration and the evacuation of clear fluid. She developed a tender area below the left costal margin, which was incised, and a left subphrenic abscess was drained, but ultimately she died.

The first of these two cases serves well as an example of what Barnard termed a right anterior intraperitoneal abscess, which is due either to perforation of the duodenum or stomach, to liver abscess, or to appendicitis. If the latter, usually the case will be of the type outlined above, where rather late operation evacuates a retrocæcal abscess. When a perforated duodenal or gastric ulcer gives rise to such an abscess usually it points in the right hypochondrium to the right of the falciform ligament; its margins are to the right and above the right costal margin, to the left the bulging falciform ligament, and below a band of rigidity and tenderness extending from the umbilicus to the right ribs where a band of omental adhesions shuts it off from the general peritoneal cavity. Gas either escapes from the stomach, or is formed in the abscess cavity, so that the centre of the dull area is tympanitic and amphoric sounds are heard over it. Similarly had the abscess in the last case I quoted been allowed to remain a few days it would have extended to the right, pushing the falsiform ligament before it, and might have pointed in the left hypochondrium as a gas-containing abscess.

DIAGNOSIS.

In my experience few conditions have given me so much difficulty as the diagnosis of this condition.

History.—We have as our first guide the history. Thus a story of continued indigestion may suggest a lesion of the stomach or duodenum as the origin of the abscess, and therefore its probable location. We may have carried out an operation for the suture of a perforated duodenal ulcer and so be suspicious of infection under the right leaflet of the diaphragm. We know from X ray evidence and from actual observation during operations that injuries of the diaphragm of which operative manipulations even of the gentlest possible degree form no inconsiderable part lead to a temporary paralysis of the affected half of the muscle, just as does any inflammatory lesion in its neighbourhood. We have to assess the importance of this factor in the causation of subphrenic infection after major upper-abdomen operations such as difficult and prolonged common bile-duct operations in fat subjects or partial gastrectomies in enfeebled elderly patients. We must constantly bear the possibility of such a result of any undue trauma and must set our ingenuity to work to devise a means by which such a paralysis may be eliminated.

As I have pointed out above, the onset of formation of subphrenic infection from a subacute perforation of a gastric ulcer may be acute, whereas the post-operative variety sets in in a most insidious manner. This is not entirely accounted for by the diminished power of reaction of such patients, and it is not easy to suggest an adequate explanation. Barnard laid great stress upon a difference in the mode of onset between the intraperitoneal abscesses from perforation and the extraperitoneal collections which result from a spreading cellulitis. The former were acute, the latter much slower. My personal experience of the latter is so small that I cannot criticise his observation.

Symptoms.—The initial symptoms are: pain, usually the first, and often localised to the spot where later pus is found. It occurs in a large majority of cases, and finally is associated with deep tenderness over the same area. Vomiting may occur once or twice in the perforative type, and hiccough is a very frequent and suggestive symptom. Several times I have seen it most troublesome and persistent until the abscess has been drained adequately.

General signs.—It is upon the general signs of suppuration that we have chiefly to rely, continued or increasing pyrexia of the rocking type, continued or increasing rapidity of pulse, a dirty dry tongue, increasing anæmia, with a complexion of the muddy kind which Barnard so happily termed "the purulent complexion." Sweating is met with frequently, but there is no characteristic change in the bowels as is met with in pelvic abscesses where diarrhœa is so suggestive a sign. I have not seen rigors in uncomplicated cases, and leucocytosis, though always marked, is usually of little value, as it may be due to the antecedent condition, and therefore cannot definitely be attributed to the subphrenic abscess. At the same time, a white count should always be done as soon as the suspicion that all is not well has been aroused. It can then be repeated, probably several times, before occasion for operation arrives. If these examinations show that the white count has fallen after operation for the initial disease—for example, appendicitis—and again risen to a high level, it affords an indication of the presence of pus of no mean value. When we have the clinical picture outlined above, we have usually no difficulty in feeling sure that pus is present somewhere. The difficulty rs in locating it and, having done this, in finding it.

l signs of subphrenic abscess.—In the early stages rigidity with deep tenderness alone may be in ce, then a swelling gradually appears over which abnormal dullness may be elicited. This may be an extension of normal liver dullness downwards and to the left, but if an abscess is present between the diaphragm and liver the latter is usually not pushed downwards, so liver dullness is not increased downwards as it is with an abscess of the liver, owing to adhesions between the lower liver margin and the parietal peritoneum. For the same reason such a swelling does not move freely on respiration. If of large size the lower thorax may bulge on the affected side, and the circumference of that side may be shown with the tape measure to be increased. Should the abscess become secondarily infected with *B. coli* or other gas-producing organisms the note over the most prominent part will become tympanitic and amphoric and coin sounds may be obtained. Rarely a peritoneal friction sound may be heard over the margins of the swelling. Usually such patients are too ill for a systematic X ray examination and often for any such examination at all, but when it can be undertaken, it may elicit most valuable information by showing that the arch of the diaphragm on the affected side is unduly raised and is immobile. Sometimes the abscess may be demonstrated as a localised dark shadow.

Thoracic signs.—The early signs are those of compression of the base of the lung, which later pass into evidence of pleural effusion which is at first serous and finally becomes purulent. Thus diminished resonance, absence of breath sounds, diminished vocal resonance and tactile vocal fremitus, with possibly a pleuritic rub, may occur in an uncomplicated subphrenic abscess. In such it may be possible to map out the dull area so as to show an upper convex margin at the level of the raised diaphragm, but shortly, as happens in two-thirds of all cases, a secondary pleurisy with effusion will complicate the simple picture of subphrenic abscess. The extent upwards over which the chest signs exist may point to the presence of an effusion, as will a horizontal upper margin of the dullness and displacement of the apex beat to the side opposite to the signs will confirm this suspicion, as such displacement never occurs with an uncomplicated collection below the diaphragm.

Spontaneous Rupture of Subphrenic Abscess.

Of Barnard's 76 cases 23 ruptured into one of the thoracic or abdominal viscera, usually the stomach or bronchus. With more exact methods of diagnosis now at our disposal this is less likely to be allowed to happen as operation will be earlier undertaken, but its possibility must be borne in mind, and when it occurs before an exact diagnosis has been possible it may help to localise the abscess. Such a method of evacuation of the abscess is not to be waited for or counted upon. As in the case of Captain R., it is often difficult to decide whether the pus is coughed up or vomited up, and if the latter, to know which part of the alimentary tract it burst through—i.e., stomach, œsophagus, or duodenum. Further, such subphrenic abscesses which as soon as they become tense can evacuate themselves are exceedingly difficult to locate, as they never become large enough to produce definite signs, and as when the air-passages are involved the pus is replaced by air, the physical signs may often become indefinite or misleading.

Value of the Exploring Needle.

Whenever signs are present which indicate that pus is tracking towards the surface either in the epigastric angle or in the loin, free incision with the knife under general anæsthesia will be the safest method for the drainage, but this condition is unfortunately rare, and in obscure cases the routine use of a wide-bore needle under general anæsthesia on a definite plan has proved a great advance. In either case under a general anæsthetic, of which gas-oxygen is the best, the patient is placed on the affected side and turned three-quarters over on to the face. The use of the exploring needle is particularly indicated when we have to deal with abscesses hidden under the right cupola of the diaphragm; here the needle is introduced boldly to a full three inches and vertical to the surface, deeply through the intercostal space where the signs are most suggestive, in the posterior scapular or mid-axillary line. *If no pus is located it may be* inserted in the space above and below up to the upper margin of dullness and as low as the costal margin. *This is repeated until all the spaces over the dull area* have been explored in the nipple, mid-axillary, and posterior scapular lines. It is often difficult to determine whether the point of the needle is above or below the diaphragm; if the blood which is drawn back into the barrel of the syringe is bright and frothy it certainly comes from the lung, though darker blood may come either from the liver or from compressed lung. Again, a sense of resistance is experienced as the diaphragm is pierced, and the exposed part of the needle or the syringe will, as pointed out by Fürbringer, move with respiration when the needle has passed through the muscle. I have not noticed that temporary inflammatory paralysis of the muscle has vitiated this sign, but this possibility must be borne in mind.

May we not assume that even under normal conditions *a needle passed into the lower four spaces to the* extent of 3 inches passes through the diaphragm, and when this is raised the subphrenic space will be reached *by such a needle even two spaces higher?* When clear or turbid is withdrawn at one depth and pus still further in, the diagnosis is clear. I have no experience *of any danger through injury to vessels or viscera.* or risk of carrying infection from the chest to the abdomen by this means. If clear fluid is drawn from the chest alone, *this is aspirated by gravity through a long fine* tube. If nothing is withdrawn the patient is returned to bed; if pus is found the needle is left in situ and *another needle introduced into the space below; if pus* is found there the first needle is withdrawn, cleansed, and inserted into a still lower space. The rib to be resected will be that below the lowest space in which pus was found. In any case this must not be higher than the eighth, as above this level it is difficult to shut off the pleura by suturing *the diaphragm to the chest* wall.

GENERAL OUTLINES OF OPERATION.

Usually there is a positive indication for preference of a particular route, but if none exist the posterior transpleural thoracic route should be chosen. By considerable practice during the war very many surgeons learnt of the value of this route in abdomino-thoracic surgery. In this instance it will be assumed that pus has been found below the diaphragm, and that the needle is still in position. At least 3 inches of the rib below the space in which the needle has been inserted is resected and the diaphragm is incised, but not cut completely through for the same extent. The upper edge of the incision into the diaphragm is then carefully sutured with a continuous catgut stitch to the upper margin of the wound through the parietal pleura and intercostals so as to shut off the pleura; then the abscess may be incised freely and a large rubber tube inserted. In spite of the above precaution on at least two occasions a secondary infection of the pleura, necessitating drainage through the same wound, has ensued in my hands. If pus has been located either by incision or with a needle through the front of the chest or the anterior abdominal wall it is best to establish counter-drainage in the loin at the most convenient spot.

CONCLUSION.

It may be often that the diagnosis of subphrenic abscess is not definitely settled until pus is found and drained. As I pointed out in the case of Captain R., *even then one may be in error* as to the relation of the abscess to the diaphragm. If an abscess is found and drained below the diaphragm it may be difficult to be *sure that it is not within the liver* and that one is, in fact, draining an amœbic liver abscess. Again, the needle may enter one of the multiple abscesses which occur in suppurative pylephlebitis, but in the stage of this disease in which abscesses of any size exist the patient is much more ill, rigors are common, and jaundice is present in its later stages. A suppurating hydatid cyst may give rise to the same signs, but its nature will at once be recognised as soon as the cyst is opened.

THE VALUE OF THE QUASI-CONTINUOUS TEMPERATURE RECORD

IN THE EARLY DIAGNOSIS AND PROGNOSIS OF TUBERCULOSIS.

BY SIR GERMAN WOODHEAD, K.B.E., M.D., LL.D.,
PROFESSOR OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE;
AND
P. C. VARRIER-JONES, M.A. CAMB., M.R.C.S., L.R.C.P. LOND.,
FOUNDATION SCHOLAR, ST. JOHN'S COLLEGE, CAMBRIDGE; TUBERCULOSIS OFFICER, CAMBRIDGE COUNTY COUNCIL.

REPORT TO THE MEDICAL RESEARCH COUNCIL.

SOME years ago,[1] supplementing the observations made by the late Professor Arthur Gamgee, we drew attention to the value of quasi-continuous *(half-minute) temperature records in the study of tuberculosis* and published a number of typical temperature charts taken from tuberculous patients. We had not then sufficient experience of these records to be able to determine their exact value as an aid to diagnosis and prognosis, but certain oft-recurring features appeared to us to be characteristic of the temperatures induced, not merely by the artificial introduction of tuberculin but also by the auto-inoculation that goes on during the progress of the disease in a consumptive patient. We have been able to follow up to Jan. 1st, 1921, the cases then described and have had the opportunity of noting not only which of them have done well but which of them, not responding to treatment, have gone steadily or intermittently from bad to worse. We have thus accumulated much information as to the value of these quasi-continuous temperature records *not only in diagnosis but in prognosis.* To the histories and temperature charts of the cases already recorded may now be added the experience gained from the study of a number of typical cases[2] which, of great interest in themselves, constitute a broader basis on which to found an opinion as to the value of the method.

Features in the Record of Diagnostic Value.

In our earlier paper in THE LANCET we called attention to the peculiar character of the auto-inoculation temperature curve, and pointed out how *closely* it corresponds to the post-tuberculin curve. Of its value as a diagnostic feature we had little doubt, and we were inclined to think that its value in prognosis might be almost as great, but for that opinion we had not, at the time, any very sound or sufficient basis. The features in these quasi-continuous records on which we laid stress as of diagnostic value were: (*a*) Somewhat sudden rise of the afternoon and evening temperature, not necessarily steady, but in jerks—*temporary* exacerbations—and with a general trend upwards; (*b*) continuation at a somewhat high level—above 99° F.—for 8 or 10 hours; (*c*) followed by a *rapid fall*, sometimes to a subnormal level; (*d*) during the whole day response of the temperature to agents inducing rise or fall—exercise, food, cold or warm drinks—much more readily and through a much wider range than in the healthy individual. A combination of certain of these features gave us (*e*) what we call a "plateau"—a long-continued temperature above 99°, commencing with a sudden rise and ending with a sudden and prolonged descent—which we *considered* to be diagnostic of tuberculosis; (*f*) elevations more or less marked on the plateau—these we compared to mountain peaks on a highland plateau. *Before taking* up the general consideration of the importance of these features it may be well to give an account of certain cases, *the early* histories of which have already been published, and of a number of other typical cases, the history of which affords corroborative evidence of the diagnostic and prognostic value of the quasi-continuous temperature record.

---

[1] THE LANCET, 1916, i., 435.

[2] In all over 200 of these quasi-continuous 12-, 24-, and 48-hour temperature records of 68 patients have been made and analysed.

CASE 1.—This patient[6] had been kept under observation from June 11th, 1914, until September in the following year. He had passed through a sanatorium, had then been placed under domiciliary treatment for a time, and allowed to do but a certain amount of work. Put on full work the patient at once began "to do badly," for though there were fewer signs of active disease than had been present when he first came under treatment he ceased to put on weight. In September the patient was still working full time, and by the ordinary methods of clinical investigation it would appear that he was holding his own, but from a study of the continuous temperature charts it was evident that the disease was progressing. These temperature curves, we now find, may be taken as representative of those obtained from some dozens of similar cases, and appear to be associated with a progressive tuberculous process. In Fig. 22 the effect of the tuberculous condition on the temperature is characteristic. A fever giving rise to a slightly convex temperature curve extends from late afternoon until 12 midnight or later. The diurnal range of variation is somewhat greater than normal, but here the rise is gradual, as is also the fall, though with this latter are associated fluctuations altogether absent from a normal temperature curve. These fluctuations appear to be due to the disturbed sleep of the patient during the earlier hours of the night. As the disease progresses there is marked alteration in the character of the curve and its diurnal variations. In place of the gradual ascent there is a sharp rise, followed at the end of the plateau by a still more rapid fall to the normal level. On the injection of a small therapeutic dose of tuberculin a "plateau" curve develops at once, the temperature remaining at or above 99°4 for ten hours, though the greatest diurnal range is only 1·3° (Fig. 23). Three weeks later, *under similar* conditions, a similar plateau (Fig. 24) is developed, and on the following day, though the plateau is still present, the diurnal range is 2·3° (Fig. 25). All this was looked upon as indicating an unsatisfactory state of affairs as regards the progress of the disease. Four months later when, though the condition of the patient's lungs appeared to be satisfactory, he was found to be working too hard, *the patient commenced to lose weight, his temperature curve* became irregular and ran too high, and the exhibition of a therapeutic dose of tuberculin was followed by a definite "plateau" reaction.[5]

Temperature Instability a Feature of Tuberculinisation.

The instability or irregularity appears to be a marked feature of tuberculinisation, whether the result of auto-intoxication or artificially produced by "tuberculin." We have since noted that, in this as in other cases, as the disease progresses the "plateau" gradually becomes more and more characteristic, until finally we have a perfect reproduction of the curve—with its daily variations and its peaks—that results from the injection of tuberculin into a tuberculous subject, human or bovine. In the case under consideration, where from the temperature curve an unfavourable prognosis was given at a very early stage, the course of the disease was carefully observed until the final issue. Here not only was the plateau a more and more distinctive feature as the disease progressed, but finally a complete inverse temperature curve, a grave prognostic indication, was obtained some time before the patient died.

CASE 2 first came under observation in 1914.[6] The patient was at work in September and October, 1915, and temperature curves on which a steadily developing plateau was recorded were obtained at intervals.[7] Following the publication of this case several other curves were obtained, all of them, unfortunately, showing a progressive development of the plateau, with well-marked fluctuations, *high peaks, and deep* depressions. From *these* temperature indications an extremely unfavourable prognosis was argued. At that time there was neither hospital nor sanatorium accommodation sufficient for our Cambridge patients, and although the man was advised to cease work he would not or could not follow this advice, and the disease progressing he succumbed to a severe hæmorrhage some few weeks later.

CASE 5.[8]—The further study of another case (G. de R.) affords additional evidence of the prognostic value of the quasi-continuous temperature curve. With physical signs of tubercle in the apex of the right lung, and marked dullness and many crepitations at the left base, the patient was transferred to the colony at Little Abington. Up to November, 1915, living an open-air life, he put on weight, and the disease became quiescent; the sputum, large in amount and swarming with bacilli when the patient was first seen, steadily became less abundant, and finally was almost negligible in quantity. The note over both lungs improved; there was a gain of 3½ st. in weight and the chest measurement increased. When the patient was beginning to improve several continuous temperature records were obtained.[9] The temperature was then somewhat high, especially between 10 A.M. and 9 P.M., rising to 99·5° at 6.15 P.M. and then falling steadily until the early morning, but was also very unstable, a glass of cold milk causing a rapid and definite depression. This patient was under continuous treatment at the colony for a period of two and a half years, some dozen records being taken during that period. He engaged in fairly strenuous work and his general condition remained so good that, at the end of the European war, on discharge from the colony he was able to return to Belgium, where he attempted to resume work. He found, however, that he was able to do a limited amount of work only, was easily fatigued, and soon broke down He was then admitted to a French sanatorium, where, under treatment, he again improved slightly. He has had several attacks of hæmoptysis, there is now marked loss of weight, and the disease is still progressing. The disease was undoubtedly retarded during his stay in the colony, but was immediately roused to activity on his return to normal life. While a refugee in Cambridgeshire he was kept under strict observation and during the whole time the disease continued to progress, though slowly. He was last heard from on Jan. 5th, 1921, when he was in fair health.

[Since the above was in type the expected announcement of the death of this patient has been received.]

Plateau with Peaks and Depressions.

The accompanying additional charts were taken from this case on Feb. 3rd and 4th, 1917. In the first (Fig. 1) the plateau is well developed, the temperature remaining at or near 100° from 3 o'clock in the afternoon until nearly 8 o'clock in the evening. There is then a gradual fall till 5 A.M., after which comes a steady rise. No very marked irregularities, peaks, or depressions appear in this record, though it is by no means so regular as a normal curve, seeming to be fairly easily affected by external influences. On the following day—at 2 P.M.—a minute dose (1/25,000 mg.) of bacillary emulsion was injected subcutaneously, and although the temperature rises no higher than on the previous day, the character of the curve is altered (Fig. 2). The plateau is more marked, the rise commencing at 2.30 P.M., and is maintained until 11 P.M., when a sudden fall is associated with a severe night sweat. Here almost the lowest point of the curve is reached between 1 and 2 A.M., after which comes a slight rise, but the lowest point (97·6°) is reached at 6 A.M. Between 9 and 10 (owing to displacement of the thermometer before micturition the curve is interrupted between 7 and 8 o'clock) the temperature is again nearly 100°, and continues between 99° and 100° until 11 P.M. In this curve steep depressions and peaks are very prominent features, and although *the* rapid fall between 7 and 8 A.M. is probably due to *slight* displacement of the thermometer, the fall from the P.M. *temperature and the rapid* rise *after the* A.M. temperature are very characteristic of a somewhat active and progressive tuberculous process, that can be held in check or delayed only by the exercise of the greatest care.

CASE 6 (M. S.) was admitted to Bourn Colony, Nov. 16th, 1916, with a temperature of 103° F., pulse 100, marked breathlessness, and great loss of weight. The patient, an orderly at a military hospital, was one of six men who had slept in bunks in one small room.[10] During his stay at the colony the patient's condition improved considerably, the signs of actively progressing disease in the right upper lobe gradually subsided, and the man was placed upon graduated work. From time to time a slight rise in the evening temperature was determined by the ordinary mercurial thermometer. A quasi-continuous temperature record extending over 48 hours was taken only when there appeared to be some indication—slight rise in temperature or complaint of fatigue after work—that such was necessary. During the whole time this patient was under observation little clinical evidence as to the course of the disease could be obtained, the physical signs giving no indication of any increased activity. After admission the patient gained weight for a time, then his weight became, and remained, stationary for several months. After 12 months' treatment and training at the colony the patient was ordered to do some little light work on the land, partly with the object of ascertaining how far a patient in this condition could perform such work, and partly with a view to testing the efficiency of the system of the After-Care Association, and arrangements were made for the reception of the patient on a farm. Hours of work, which did not exceed six a day, were planned out and a start was made. For a time all went well. Clinically the patient's condition remained much the same, but gradually, as there was some loss of weight, it was concluded that there was extension of the disease and the patient was readmitted to the Papworth Colony, where more exact observations could be made and further temperature records taken.

The first of these temperature curves (Fig. 3), obtained six days after the return of the patient to the colony, at once afforded evidence that the disease was progressing. Early in the day the temperature rose to 99° and continued above that point for 12½ hours—to 10.15 P.M.; then followed a broken, irregular fall to 98° at 6.30. A second temperature curve (Fig. 4), taken 24 days later, was equally discouraging. The plateau, extending from 12.30 P.M. to 11.45 A.M., with a break of two hours, during which the temperature fell to 98·7°, was imperfect, but the "toothed," "peaked," or "wavy" character of the curve was very marked. It was evident that here auto-inoculation was responsible for the "temperature," for when a minute dose of bacillary emulsion was injected no greater reaction was obtained, though the

[10] Subsequently, though at different dates, all the other five were admitted to the colony, each with some evidence of tuberculous disease.

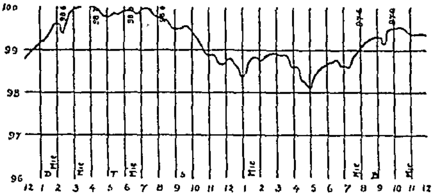

FIG. 1.—G. de R., aged 23. Record taken Feb. 3rd-4th, 1917. This shows a ten hour "plateau," with no well-marked peaks. The diurnal range of temperature is only 2°, but the curve indicates the presence of a somewhat active tuberculous process. This and the following quasi-continuous records are all taken with the thermometer in the rectum. *The figures at the upper margin of the diagrams indicate the mouth temperatures.* The temperatures are given from noon to noon in degrees Fahrenheit. B = breakfast; D = dinner; T = tea; S = supper; MIC = micturated.

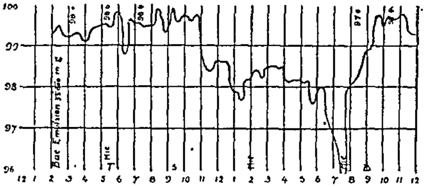

FIG. 2.—G. de R. Record taken Feb. 4th-5th, 1917, after the injection of 1/25,000 mg. *bacillary emulsion. There is little alteration* in the period over which the plateau extends, but the temperature is less stable, the peaks are more marked, and at the end of the plateau there is a sudden fall, synchronous with the development of a night sweat.

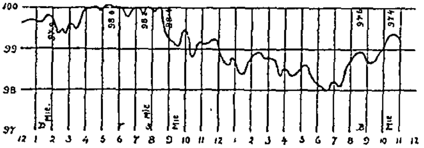

FIG. 3.—M. S., aged 18. Record made Jan. 25th-26th, 1917. Shows a plateau extending over a period of (more than) eight and a half hours. There is also some irregularity of the curve, but there are, *as yet, no marked "peaks." The diurnal range is only 2° so long* as the patient is confined to bed. The curve is that associated with a progressing tuberculosis and unfavourable prognosis.

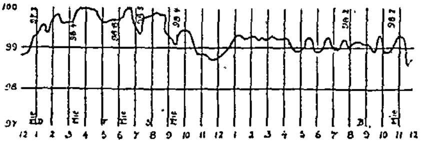

FIG. 4.—Another record from M. S. three weeks later, Feb. 19th-20th, 1917, in which the plateau is (eight and three-quarter hours) marked, peaks are more prominent, and the diurnal variation is only 1·3°, but the general level is very high. There is only slight remission during the night and morning hours.

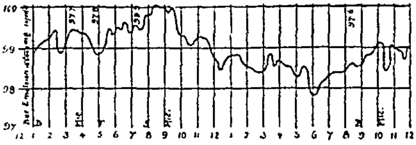

FIG. 5.—Another record from M. S. taken Feb. 20th-21st, 1917, after *24 hours' complete rest and the injection of 1/100,000 mg. bacillary* emulsion. The plateau is still marked, though at two periods the temperature falls a couple of points below 99°. The diurnal variation is 2·2°. *In all three records* the minimal temperature is considerably higher than normal.

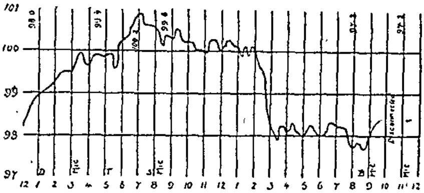

FIG. 6.—*Another record from M. S. made on April 11th-12th. Here* the disease is progressing rapidly, as evidenced by high temperature, broad plateau, well-marked peaks, and sudden fall where night sweat occurs. *Disease very advanced and actively* progressing. Diurnal variation 3°.

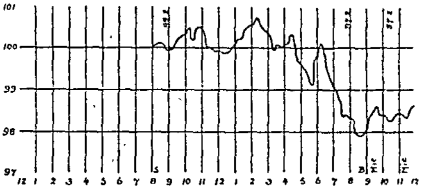

FIG. 7.—Record from M. S. made five days later, April 16th-17th, 1917, with plateau prolonged to later morning hours, well-*marked peaks, and depressions and sudden fall, with late night* sweat. Diurnal variation, 2·9°. Inverse temperature; patient nearing end.

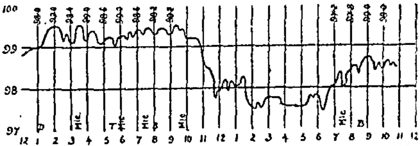

FIG. 8.—W. T., aged 15. Record made June 10th-11th, 1917. Plateau nine and a half hours, with well-marked peaks and rapid *night-sweat fall. Diurnal variation 2°,* and some instability throughout the day. Prognosis unfavourable.

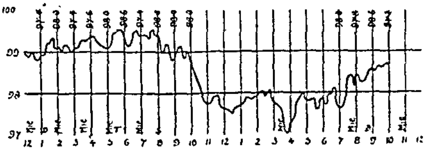

FIG. 9.—A second record from W. T., made June 13th-14th, 1917. Plateau seven hours, with night-sweat fall at 10 P.M. Curve very irregular throughout, easily affected. Diurnal range of variation 2·5°.

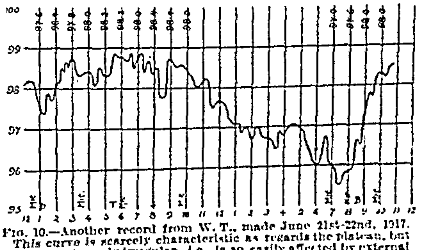

FIG. 10.—Another record from W. T., made June 21st-22nd, 1917. This curve is scarcely characteristic as regards the plateau, but it is so extremely irregular—i.e., is so easily affected by external influences, meals, micturition, &c., and the diurnal range is so great (3·3°), that without the plateau this curve must be looked upon as indicative of a progressing tuberculosis.

curve (Fig. 5) became slightly more irregular. The plateau in this instance extended over a period of 11 hours, after which the temperature fell slightly and irregularly from 99·3° at 11.15 P.M. to 97·8° at 6 A.M.

On April 11th–12th further evidence of the progressive nature of the disease was obtained (Fig. 6) in the plateau—on which well-marked peaks developed—followed by a rapid fall during a night sweat and an irregular line marking long continued low temperature. There is no rise between 3.30 and 9 A.M., probably because the patient is asleep. The plateau period (temperature above 99°) lasts for 13 hours—1 P.M. to 2 A.M. The highest point is reached, 100·9, at 7.15 P.M. The sudden fall from 101·1° to 98·9° between 2 and 3.3 A.M. is very typical of a night sweat fall. The whole curve is curiously toothed and the chart again resembles very closely that of a tuberculin reaction temperature of a bovine suffering from extensive progressive tuberculosis. On April 16th–17th, 1917, an "inverse" temperature (Fig. 7) makes its appearance. The patient's temperature was high, 100° at 8 P.M., when the tracing was commenced. The line followed a regular plateau course, at or above 100°, from 8 P.M. to 7 A.M., at 2.20 A.M. running up to 100·7°. At 6.15 A.M., after a "night sweat," there was a sudden fall to 97·9° between 8 and 9 A.M.; this was followed by a rise to 99·4° at 6 o'clock on the afternoon of the 17th.

Temperature Record More Trustworthy than Signs and Symptoms.

We are convinced from a study of the series of quasi-continuous temperature records here figured that considerably more reliance is to be placed on them than on physical signs and clinical symptoms however accurately noted and carefully interpreted. The instability of the temperature, especially when a plateau is developed must, apparently, be accepted as a reliable indication of increased activity of the disease, whether physical signs can be made out or not. These records, it is true, were made only after some special indication of the necessity for so doing had arisen, but in each instance the special curve appears to result from auto-intoxication or auto-inoculation. This, however, is exactly the factor we wish to determine, and here the records indicate most clearly the successive doses of tuberculin which the patient has, from time to time, administered to himself through the work or exercise prescribed for him. On readmission to the colony some improvement in the general condition of M. S. took place, but from such time onwards the clinical signs began to point to an extension of the disease, the temperature records continuing to substantiate our deductions from the clinical signs. Again and again "tuberculin temperatures" were recorded, highly irregular plateaus made their appearance and, finally, a true inverse temperature curve was obtained. The plateau had taken complete control of the range of temperature and, as in other fatal cases, gave an indication of the approach of the end, many weeks—nay months—before the final issue was determined, April 19th, 1919. The case is interesting from the fact that the period of observation extended throughout the whole course of the disease—some years; and also that quite early in the disease the character of the continuous temperature record enabled us to make not only a diagnosis as to the extent of the disease but to anticipate its probable course, for it has been found that in all records of a number of fatal cases of tuberculosis collected during the past eight years the persistence of a plateau temperature, especially when on this are superposed marked fluctuations, is a sure indication of active disease, whether this can be diagnosed by means of the stethoscope or not.

CASE 7 (W. T.) was admitted to Bourn Colony, May 11th, 1917, as an early "contact case" of pulmonary tuberculosis; not only has his mother since died from pulmonary tuberculosis, but a sister has recently succumbed to the same disease. In this patient the consumption early assumed a very virulent form, for although the activity of the process was retarded by rest and treatment—the patient gained 17½ lb. in 2½ months—the disease again began to progress as soon as the patient was allowed to work anything beyond very short hours. Temperature records were taken during the 2½ months between 11/5/17 and 31/8/17, at the time the patient was putting on weight. Eighteen month later, February, 1919, the patient died.

In Fig. 8 we have the first of a series of curves showing, in the continued and regular level of the "plateau" between 2 P.M. and 10 P.M., the effects of the auto-inoculation of the patient, followed by a steep fall of a degree and a half within two hours, after which, at 6.20 A.M., the lowest point is attained. A similar record was obtained three days later and again ten days later (Fig. 9). Instead of the usual diurnal variations, we have here a prolonged period during which the temperature remains at almost one level, broken only by sharp peaks and depressions such as are so commonly met with when tuberculin is injected into tuberculous cattle. The A.M. temperature usually falls (Fig. 10) and behaves very much as does the normal temperature, but in a record taken June 24th–25th the difference between the A.M. temperature and the P.M. temperature is less than normal (Fig. 11).

CASE N. was admitted to Bourn Colony on April 21st, 1917, with definite signs of extensive tuberculous disease of the lungs and peritoneum. The patient's whole physique was flabby and his general condition very poor. After keeping him under observation for a month it was decided, as accommodation was then limited, to discharge him from the colony, and on May 25th, 1917, he was sent home and placed under domiciliary treatment. He was dead within six months.

Curve of Rapidly Progressing Tuberculosis.

The temperature curves from this case are very characteristic and of great interest. Taken 12 and 13 days after admission, they indicate a rapidly progressing tuberculosis. Though the temperature only once reached 100°, the plateau (above 99°, Fig. 12) extended for 11 hours during the first 24 hours, May 3rd and 4th, and 8 hours on the following day. The temperature then fell to subnormal, 96·2° at 5.30 P.M. on the first day and 96° on the following day at 8.30. Here the plateau, the range of the diurnal variation, 5·8° on May 3rd–4th and 3·6° on May 4th–5th (Fig. 13), combined with the extreme irregularity of the curve left no doubt as to the active and progressive character of the tuberculous process.

CASE S. D. was admitted Dec. 23rd, 1916, in a very advanced stage of pulmonary tuberculosis, both lungs being considerably involved. So ill was the patient that he was confined to bed during the whole of his stay at the Bourn Colony, suffering from severe night sweats, commencing when the night temperatures were at the highest. He remained under observation in the colony for about a month only, and died shortly after discharge—Feb. 25th, 1917.

In the three records here given we have ample evidence of the extreme activity of the disease in its later stages—five or six weeks and then four weeks before the death of the patient. In Fig. 14 it is seen that the temperature rises rapidly, but very irregularly, from 98·4° at noon to 100·9° at 7.15 P.M. It then falls, with a severe "night sweat," to 100° at 9.30, from which point there is a steady rise to 103·7° at 4.30 A.M., giving a diurnal range of 5·3°, followed by a somewhat intermittent fall to 99·7° at 10.40 A.M. This complete inversion of the usual curve is, as already noted, very characteristic of the late stage of a rapidly progressing pulmonary tuberculosis. The second record (Fig. 15), made 11 days later, is especially interesting in that not only is there a high temperature, an irregular curve, a wide range, and a very rapid fall after a night sweat at 3 A.M., but a very high plateau (over 102°) extending between the hours 2 P.M. and 5 A.M., apparently the result of severe auto-inoculation. The fall from the highest point of the plateau at 3 A.M. is both rapid and irregular. Here we have a semi-inverse temperature extending from 101·3° at 12 noon to 103·6° at 3 A.M. and falling with breaks to 99·3° at 11 A.M. On the following day a curve (Fig. 16) of a somewhat different type, but still very characteristic, is obtained. Commencing at 98·2° at 1 P.M. there is a continuous and regular rise to 101·5° at 6 P.M.; after this the rise becomes irregular, with marked dentations, until at 12.30 A.M. it reaches 103·6°. At 1.30 A.M. a night sweat commences and the temperature begins to fall, though slowly, reaching 103° at 2–4 A.M., 102·2° at 5 A.M., 102° at 7 A.M., 100·3° at 9.30 A.M., and 100° at 12 noon. In 12½ hours there is a rise of 5·6°, followed by a fall of 3·8° in 10½ hours, the temperature remaining at or over 100·3° for a period of 21½ hours. This curve corresponds very closely to the post-tuberculin curve obtained from a calf in an advanced stage of tuberculosis.

CASE L. P. was admitted to Bourn Colony June 26th, 1916, as a case to be kept under observation. Two months previously he had suffered from a severe attack of influenza, but when admitted was quite convalescent. Owing, however, to the *length of time* that the influenza symptoms had persisted it was feared by his medical attendant that the patient might have developed pulmonary tuberculosis. During his stay at the colony he had no cough and no rise of temperature, though frequent records were taken. There was a gain of 9½ lb. weight, the patient reaching his normal weight in a very short time. He was able to do a full day's work without the slightest fatigue, and was soon discharged fit to continue his trade of cycle repairing. Since leaving the colony he has not had a day's illness, and at the present date (5/1/21) he is well and strong and doing a full day's work.

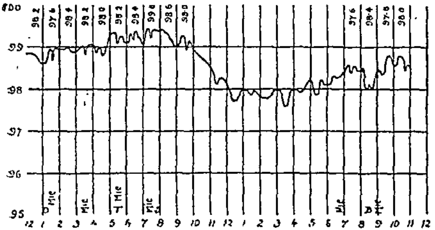

FIG. 11.—A fourth record from W. T., made June 24th-25th, 1917. Nine hours' plateau, with many peaks and depressions followed by a night-sweat fall. Diurnal range 1·8°, but high mean.

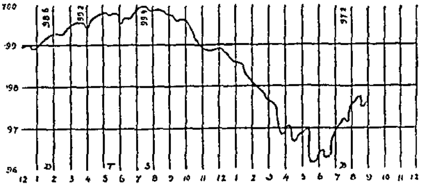

FIG. 12.—N., aged 20. Record made May 3rd-4th, 1917. Plateau eleven hours, but with no very marked peaks or depressions. The fall from 10 P.M. is very steady and regular until 3.30 A.M., when period of profound sleep is past. Diurnal range 3·8°. Prognosis very unfavourable.

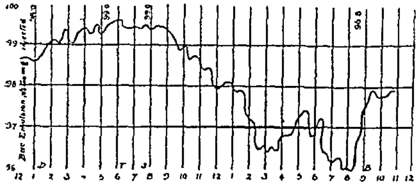

FIG. 13.—A second record from N., made May 4th-5th, 1917, after the injection 1/100,000 mg. bacillary emulsion. Seven and three-quarter hour plateau, irregular curve, early morning sweating, with rapid fall of temperature between 1.30 and 2.30 A.M. Diurnal range 3·6°. Here the natural tuberculinisation is so great that the addition of the comparatively small amount of bacillary emulsion affects the curve but slightly.

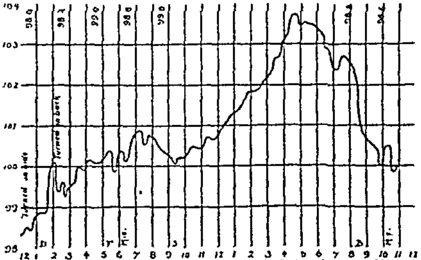

FIG. 14.—S. D., aged 25. Record made Feb. 2nd-3rd, 1917. Characteristic "inverse temperature." Prognosis very bad.

A Normal Temperature Record.

In the record (Fig. 17), taken from this patient at the Pathological Laboratories on June 20th, 1916, before he was admitted to Bourn, we have a characteristically normal temperature curve. There is no plateau and little irregularity of the curve, and although the diurnal range is nearly 2° it is obvious that no auto-inoculation effects are present. To further test the matter a diagnostic dose of bacillary emulsion was injected at 12 noon on June 21st. This *gave rise to no*

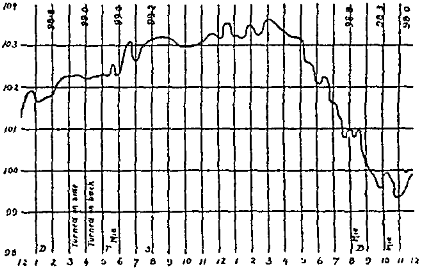

FIG. 15.—A second record from S. D. 11 days later, Feb. 13th-14th, 1917. Even though temperature runs between 93·3° to 103·6° during the 24 hours, the plateau, with peaks and depressions, still persists. The movement of the plateau to the right is here very characteristic of the "inverse" or "half inverse" temperature.

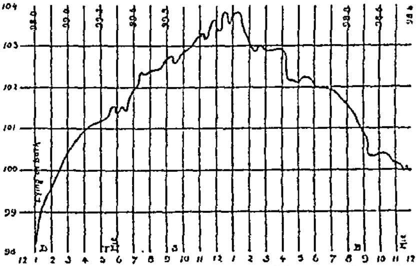

FIG. 16.—Another record from S. D. resembling very closely the post-tuberculin curve taken from a calf in a very advanced stage of tuberculosis. *Diurnal range, peaks, and depressions well marked.* Diurnal range 5·6°.

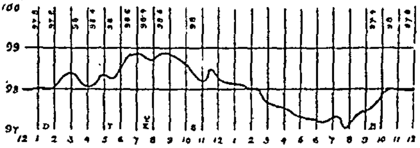

FIG. 17.—L. P. Admitted as doubtful case of post-influenzal tuberculosis (?) Record taken June 20th-21st, 1916. A "normal" temperature curve. *Regular curve with normal* diurnal range and variations with no exaggerated peaks or depressions. Diurnal range 1·8°.

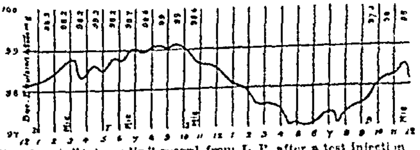

FIG. 18.—A "tuberculin" record from L. P. after a test injection of 1/100,000 mg. of bacterial emulsion. No plateau, merely a very slight and temporary rise of about three points. Still a "normal" curve in all respects. Diurnal range 2·1°. Diagn [illegible] tuberculous," afterwards confirmed.

plateau temperature (Fig. 18); the fall from the highest point at 9.30 to the lowest at 5.30 A.M. is well graded, the rise of the A.M. temperature is equally gradual and steady, and there is little or no exaggeration of the "teeth" of the curve, which, even after the injection, shows nothing but an immediate slight rise of 0·3°. The whole curve undoubtedly justifies a negative diagnosis —absence of any tuberculous process.

CASE K. S.—This patient, a scientific instrument maker, the brother of M. S. (Case 6), was examined in December, 1916, as a "contact" of his brother, for though he had not been working with him at the Military Hospital, he had shared a room with him at their own home. The general appearance of the patient was far from robust. He was thin and not well developed, his frame being considerably slighter though more wiry than that of his brother; indeed, he looked the more delicate of the two. He protested, however, that he was "quite well." In the chest there were no physical signs, and no definite evidence of pulmonary mischief. It was thought, however, that here was a suitable case for observation, especially as there was a strong probability that infection might have taken place. This, coupled with the delicate frame of the patient, made him a suitable subject for a control observation, and he was sent to the colony, where for 5½ months he was kept under close inspection in surroundings and under conditions similar to those in which his brother was living. Quasi-continuous temperature records were made at intervals. During the above period he gained 16¾ lb. in weight, and at the end of it he returned to his work with the Cambridge Scientific Instrument Company, coming to the dispensary for examination from time to time. No signs of tuberculous disease have ever been found, and at the present date the man enjoys good health and is doing a full day's work.

On Jan. 23rd–24th, 1917, the temperature of the patient running about 99° from 12 noon until 7.15 P.M., a small dose (1/100,000 mg.) of bacillary emulsion was injected just before 8 P.M. This was followed (Fig. 19) by a slight rise to 99·7° at 8 P.M., and then by a steady fall to 99° at 11.50 P.M., and by a further fall, following a normal line until 2.45 A.M., when the lowest point, 97·3°, was reached. Then began a rise, at first slow until 7 A.M., and then more rapid until 11 A.M., when 99·7° was reached. On Feb. 7th–8th 1917, in the same case (Fig. 20), the temperature, 98·2° at 12 noon, rose at 2.30 P.M. to 99°, reaching 99·9° at 6 P.M. Then followed a fall to the lowest point reached, 96·4°, at 12.15 A.M., followed by a slight rise to 97·3° at 1 A.M., a fall to 96·8° at 4 A.M., and an irregular rise to 99·7° at 11 A.M. It will be noted that here there is no continued "plateau," and that although the curve is irregular it is by no means characteristically "tuberculous" in any other respect. In a second group of curves any well-defined plateau is still absent, for although the temperature on Feb. 24th–25th (Fig. 21) runs above 99° for nearly ten hours between 12 noon and 12 midnight, it twice falls below that level—at 5 o'clock in the afternoon and between 9.30 P.M. and 10.45 P.M. At no time does it rise beyond 99·7°, and during the greater part of the period it is below 99·3°. Between 12.30 A.M. and 1.15 A.M. there is a fall of 0·7°., the temperature then going down steadily until 7 A.M., when it reaches 97·9°, and then rises equally steadily to 99·6° at noon. With the object of confirming or correcting these observations another temperature record was taken on April 2nd–3rd, 1917. Here, again (Fig. 22), no plateau is seen; the rectal temperature does not continue above 99° for more than six hours; 98·8° at 12 noon, 99° at 2 P.M., it reaches the highest point, 99·6°, at 6.30 P.M. By 8 P.M. it had fallen to 99°, at 10 P.M. to 98·3°, and then, with slight intermissions, to 96·8° at 5.45 A.M. and 96·6° at 8 A.M., after which there is a steady rise to 98·6° at noon. In the afternoon, between 3 and 4 o'clock, the injection of 1 mg. of old tuberculin was followed by no tuberculin reaction (Fig. 23). There was a slight—practically normal—rise of temperature to 99·5°, followed by a steady, though irregular, fall to 97·6° at 11.20 P.M. and a further fall to 96·9° at A.M., after which the temperature began to rise, and at noon had reached 98·7°. During the whole period none of the characters of a true tuberculin temperature were noted. The records obtained from this case, K. S., a non-tuberculous patient, served as admirable controls for comparison with those of his brother, M. S., a markedly tuberculous patient. Both had been and were observed under exactly similar conditions. All records were taken at similar intervals, and external rs, diet, temperature (summer and winter) were ical.

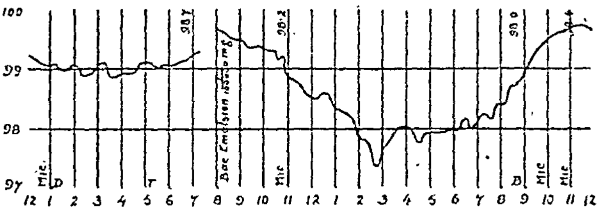

FIG. 19.—K. S., aged 20. Record made Jan. 23rd–24th, 1917. A contact case, brother of M. S. (Figs. 3–7). Tested with 1/100,000 mg. bacillary emulsion. Diagnosis doubtful.

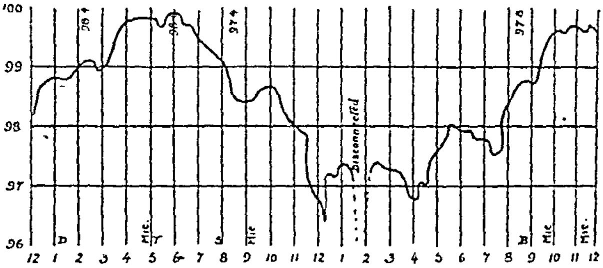

FIG. 20.—Record from same case (K. S.), Feb. 7th–8th, 1917. Plateau only four and a half hours, and curve very steady and regular. Diagnosis still "doubtful, but, if tuberculous, prognosis favourable."

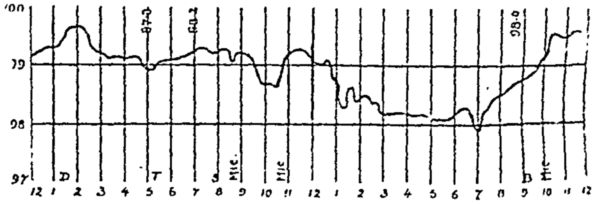

FIG. 21.—Record from same case (K. S.), Feb. 24th–25th, 1917. Morning temperature rather high. Diurnal range 1·7°. Plateau (?) but temperature is steady and not much affected by external influences. Diagnosis still "doubtful, but, if tuberculous, prognosis good."

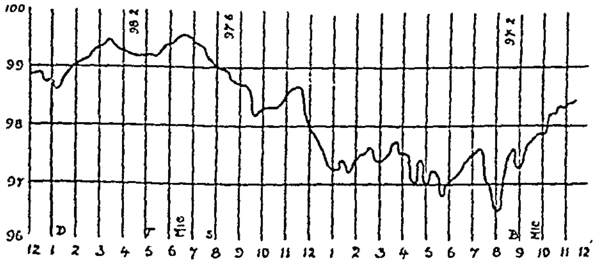

FIG. 22.—Record from same case (K. S.) five weeks later, April 2nd–3rd, 1917. Plateau contracted to seven hours. No marked peaks or depressions. Irregularities in the curve occur only when patient is restless or awake. No night sweat with early morning fall. Diurnal range 3°.

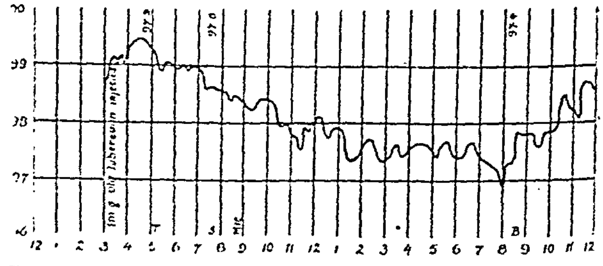

FIG. 23.—Test record from same case (K. S.), April 2nd–4th, 1917, after injection of a test dose of bacillary emulsion 1/100,000 mg. No plateau, curve somewhat more irregular than usual, but the curve now follows quite normal lines. Diurnal range 2·6°. Diagnosis: No tuberculosis.

The Advent of Thermometry.

Fever or pyrexia has long been associated with various forms of pulmonary consumption and tuberculosis, but with the advent of thermometry it assumed a special importance. Aitken,[11] following Wunderlich,[12] drew attention to the fact that in tuberculosis, especially in its acute form, the persistence of a uniformly high temperature, quite apart from other signs, is sufficient indication that there has been no arrest in the progress of the disease. Aitken, however, realised the difficulty of making a definite diagnosis or prognosis on a single observation. In a series of unsigned articles dealing with Wunderlich's thermometrical work[13] the importance of a rise of temperature in tuberculous conditions —e.g., "while tubercle is being deposited in any of the organs of the body the temperature of the patient is preternaturally raised"—is strongly insisted upon, this rise being "a measure of the rapidity with which tubercle is being deposited in any of the organs of the body." Again, in 1860 Ringer and Rickards[14] demonstrated that the temperature of the body is always preternaturally elevated, while tubercle is being deposited in any of its organs. They hold, moreover, that if there be a chronic elevation of the temperature, and this be not due to rheumatism, ague, suppuration, or chronic induration of the lung, it must be looked upon as being due to a tuberculous deposit in the body. With the advent of the tubercle bacillus temperature records became of still greater importance, especially as bearing on the progress of the disease.

In 1893 J. Kingston Fowler[15] made a valuable contribution to our knowledge of this subject, drawing attention to the indications as to the progress and activity of the tuberculous process offered by the degree and type of pyrexia. He pointed out that the "tuberculosis" daily temperature curve is usually characterised by pyrexia commencing in the afternoon, gradually increasing to a maximum at 8 or 10 P.M., and then falling continuously until the early morning, when the thermometer may register one, two, or even three degrees below normal. He admits that this type of pyrexia is not confined to tuberculous disease, although it certainly occurs in connexion with it with special frequency, *its presence often first indicating the real nature of a doubtful case.* He is of opinion that no satisfactory explanation of this pyrexia has ever been given, although "when occurring in a case of pulmonary tuberculosis with a rapid disintegration of the lung, it is generally ascribed to septic absorption," though a similar rise in cases of tuberculous pleurisy and tuberculous peritonitis may be met with. He looks upon this fever as the "expression" of an attempt on the part of the organism to deal with and destroy the product of the *Bacillus tuberculosis*, or of "a direct effect on the heat-regulating centres of the absorption of the toxic material ...... a sudden increase in the area of lung affected, or an accession of activity of the morbid process without definite signs of extension, is almost invariably marked by the occurrence or increase of pyrexia."[16]

A moderate rise with a distinct morning fall "indicates a progress of infiltration, with foci of softening, or, again, when the regularity of the evening rise and the morning fall is disturbed in any way; as when there is a sudden increase in the evening fever associated with a less marked morning remission, or when, on successive days, the lowest point touched gradually recedes from the base-line and regularity is replaced by marked variability, we are rarely wrong in concluding that an extension of the morbid process has occurred, and conversely it is scarcely necessary to state that between such periods of pyrexia there may be long intervals marked by absence of fever during which there is either partial or complete arrest of the morbid process."[17]

"Normal" and "Inverse" Types of Pyrexia.

He notes, too, that in fibroid tuberculosis, a chronic condition in which tuberculous foci, even when present, are isolated, the disease is sometimes "characterised by hypopyrexia which may persist almost throughout the case even during periods of extension of the disease within the lungs,"[18] the temperature in certain of these cases never rising above 98·4° F. In an equally exhaustive paper, Dr. S. Vere Pearson[19] records a number of observations of great interest and value. He divides the temperature met with in his cases of tuberculosis into four groups, for each of which he constructs a curve; one for a type of temperature which he speaks of as "normal," a second as "half-normal," a third as "half-inverse," and a fourth as "inverse." He maintains that if a sufficiently large number of cases of pulmonary tuberculosis be studied, examples will be found coinciding with, or approximating to, one or other of the following types: (i.) the lowest temperature is met with at 12 noon instead of first thing in the morning; (ii.) the highest temperature is reached at 9.45 P.M. instead of 6.45 P.M.; and (iii.) an entirely erratic type of temperature, sometimes inverse, sometimes highest at noon and sometimes lowest at noon. The third of these groups he looks upon as indicating a bad prognosis, the late high temperature (ii.) as being of less grave significance and (i.) of least grave significance.

Dr. Pearson was evidently confronted with the same difficulty that early presented itself to us during the course of our work—the difficulty of determining the early morning temperature of his patient, a difficulty which led us to search for the *normal diurnal variation.* We then found that temperature is, to a certain extent, even in the normal individual, a matter of custom and habit, but that, speaking generally, the lowest temperature is usually recorded when the bodily and functional activities of the individual are at their lowest ebb, and if, for any reason whatever, these have been subject to excessive stimulation or have been compelled to pass through an abnormal cycle there may be, during the period of exhaustion, a lower or the lowest temperature at a period other than that at which it is usually met with under normal conditions. It has been generally accepted that the early morning temperature of a patient with quiescent or healed tuberculosis is lower than that of a healthy person, and that the rectal temperature after recovery from a relapse may be several points lower than the temperature met with, as a rule, after recovery from the primary trouble. Sometimes it is the morning temperature alone that is lower; sometimes *all the rest-temperatures are lower*—indeed, Vere Pearson lays stress on the small excursion that occurs after a return to health, but we are inclined to the opinion that no such restriction of the excursion may take place and that the mistake involved has arisen because after rest and treatment the "minimum" temperature *is usually recorded after the morning rise has commenced.* No definite and reliable temperature curve can be built up on observations taken at fixed times, even when taken every four hours, and certainly not when taken only four times a day.

Healthy Diurnal Variation and Range.

When we first took up our investigations on the temperature of the animal body we long remained in considerable doubt as to what should be looked upon as a normal temperature and what its normal diurnal variations and range. Most of the earlier observers, finding themselves confronted with the same difficulty, made efforts, in many instances very successful efforts, to obtain information on these points, and some have recognised the relative movements of the several temperature points, noting that under certain conditions the highest point might be attained an hour or two earlier or an hour or two later than usual in the evening and, similarly, the lowest point an hour or two earlier or later in the morning. In spite of this we find that the times at which temperatures are taken are usually "fixed." Consequently the highest and lowest points are frequently missed, and deviations from the normal indicative of altered conditions, remain unobserved.

[19] The Temperature as a *Guide to the* Treatment and Prognosis of Phthisis, THE LANCET, 1909, ii., 852. At the time the part of our first paper dealing with clinical cases was written (THE LANCET, 1916, i., 496, et seq.) we had, owing to war conditions, no access to much of the literature of the subject. We have since read Dr. Pearson's article in which he gives his observations on the fever of phthisis and describes most fully an erratic type of temperature which corresponds very closely to the fluctuating temperatures of our records.

In his paper Vere Pearson sets up a somewhat arbitrary standard which, however, in the absence of continuous records, probably affords a good "working rule"; he says that fever is present when the morning temperature reading is above 98°, the evening record above 99·4°, and that a call for care and rest is then indicated. "The heightening evening temperature," he says, "may be the indication of the slight remains of activity, but a raised morning temperature means more than this."

To the series of normal temperature curves already published[20] we now add others; two (Figs. 16 and 17), obtained from a patient who, after an attack of influenza, was kept under observation as a suspected case of pulmonary tuberculosis; and five others from a "contact" who never developed tuberculosis (Figs. 18–22). In the former case the highest temperature attained is between 7 and 9 P.M., 98·8° on the one day, and between 7 and 10 P.M., 99° and 99·1° at 7.45 A.M. on the first day, and 97·1° at 4.30 A.M. the next day. The injection of a dose of bacillary emulsion causes a rise of only 0·2° at the highest point, though there appears to be a slightly higher temperature for a period of eight hours. There is no sudden rise at any point, the gradient of the fall is very gentle, no "plateau" is developed, and the irregularities characteristic of a tuberculin curve are absent.

Time of Highest and Lowest Daily Reading.

In the healthy individual any temperature of 98° or below has been accepted as a normal morning reading. We should place the figure for a rectal temperature nearer 97°, but it is evident, from a study of the various records of healthy individuals of different ages, that even in the same person the minimum reading varies on different days at the same hours in the morning even under similar conditions, except as regards the period at which the individual is enjoying his most profound sleep, the time at which all the bodily functions and activities are most in abeyance. It must, of course, be borne in mind that as a rule whilst the quasi-continuous records are being taken the patient is confined to bed, and that he is only kept in bed because there is need for rest during the course of treatment. The measure of rest, however, complete or incomplete, can be accurately determined by a study of the curves obtained.

It is obvious, from what has been stated above, that the difficulty of determining the exact time at which the temperature should be taken is completely eliminated by the adoption of the continuous or quasi-continuous method. Vere Pearson draws attention to the fact that the lowest temperature for the 24 hours, not only in the healthy individual, but in most cases of tuberculosis in which the disease is not active, occurs between the hours of 1 and 4 A.M. Our experience enables us to agree with this, except that this lowest point may be reached as much as three or four hours later. Again, although we are in *general* agreement with his statement that the highest daily reading is usually between 3 P.M. and 8 P.M., our experience is that the highest daily reading is sometimes earlier than the above and sometimes later.

Deductions from Morning and Evening Rectal Measurements.

We have made careful study of the information as to the temperature changes recorded by later observers, amongst others, F. Burton-Fanning and S. G. Champion,[21] K. Turban,[22] F. R. Walters,[23] Arthur Latham,[24] and A. C. Inman,[25] as occurring in different types of pulmonary tuberculosis. There appears to be a consensus of opinion that where rectal temperatures are taken—and all, with the exception of Burton-Fanning, agree in insisting that the rectal temperature, and that only, is reliable—(i.) any slight daily repeated rise above the evening normal must be accepted as indicating the presence of active tuberculous disease; (ii.) a morning rise, even comparatively slight, whether accompanied by an evening rise or not, may be a still graver sign. Most observers draw attention to the fact that this morning rise is frequently the indication of an inverse temperature such as may be associated with cases of acute miliary tuberculosis or very advanced cases of rapidly caseating catarrhal pneumonia—the terminal phase of so many types of pulmonary tuberculosis.

Vere Pearson maintains that here there may be but slight difference between morning and evening temperatures and, further, that were single morning and evening temperature only taken at the usual times they would almost certainly be accepted as normal. There appears, however, to be general agreement that patients in whom the temperatures show little variation, even at a low level, during the 24 hours, often possess little reactive power and "have to be dealt with very cautiously." (iii.) The continuous temperature in which though morning and evening temperature are both somewhat higher than normal, that of the evening not being raised so much as is that of the morning, indicates a commencing inversion. A marked evening rise, especially when accompanied by irregularities—remittent and intermittent; (iv.) is characteristic of acute caseating tuberculosis; (v.) a normal or subnormal temperature is met with in cases of chronic fibroid tuberculosis and, especially in somewhat more active disease, following a raised evening temperature.

It has been pointed out, repeatedly, that in acute miliary tuberculosis there is an increase of pyrexia usually occurring after midday and marked by great irregularities "the maximum being observed between 8 and 10 P.M., followed by a remission accompanied by profuse sweats in the early morning." Again, the "inverse type" in which the evening temperature is lower than the morning temperature is said to be characteristic of this form of tuberculosis. All are at one, further, in holding that wherever the type of temperature curve has become changed in any way—i.e., has departed from the normal, ever so slightly—the patient must be advised to "make haste slowly." We agree[26] with Vere Pearson, that by a careful study of rectal temperature the onset of relapses and complications are recognised more readily and certainly than by any other method:—

> "It is of particular importance in respect of the early recognition of a relapse to remember that not infrequently the physical signs of the extension of the disease in the chest are only to be found after the symptoms of the set-back have subsided. Hence, anything which helps towards an early recognition of tendency to relapse is of the utmost importance in treatment, because with skill the inclination towards renewed activity or extension of the disease can be checked, and thereby often, I feel sure, a definite set-back warded off.[27]

Temperature Observation as an Aid to Early Diagnosis.

We go further, however, for, from our own experience, these temperature observations are of even greater importance in the *early diagnosis* of tuberculous disease, and we hold that the commencement of the process assumes to the infected organism the same relation that a relapse bears to the patient with the developed disease. In the one case we are on the outlook because we have already obtained evidence of the presence of the disease, in the other we may frequently obtain the evidence do we but search for it.

[27] Pearson: THE LANCET, 1909, ii., 853.

It will be readily understood, then, from what we have stated, *that it is not always an easy matter* to determine by single routine morning and evening temperature readings whether a febrile condition is present or not. Further, *it is now recognised that in night* workers who rest during the day a "normal inverse" temperature obtains as soon as a habit is formed. We are of opinion, moreover, that the inverse temperature met with in acute miliary tuberculosis of the lung and similarly present in the advanced and rapidly progressing *catarrhal pneumonic type of pulmonary* tuberculosis is due, in part at any rate, to the disturbance of the cycle of the functional activities that accompanies the rapid extension of the tuberculous process. In both types of tuberculosis the presence of the inverse temperature affords evidence that the disease is assuming an acute progressive form and that *there is little prospect of any permanent arrest* of the disease.

Marcus Paterson has long held *that the patient with* large cavities—cavities bounded by walls of fibrous tissue—in the lung must be looked upon as an individual resistant to the disease. *In such a patient the disease has progressed slowly*; there may have been several or many exacerbations, but these have given rise to *comparatively slight* constitutional or physical manifestations but to *marked* proliferation of the connective-tissue cells. *So consistent have been our observations on the* cases treated at the Bourn and Papworth colonies that, taking the cases collectively, fibroid, miliary, and pneumonic caseous cases, the slowly developing and resistant or fibroid cases, and the more rapidly progressive cases, we *think it may now be accepted that the pyrexia varies almost directly with the rapidity* and extent of the breaking down of the tissues through the activities of the tubercle bacillus, the breaking down of the bacilli, and the absorption of the products of these lytic processes by the surrounding *tissues and inversely* as the "resistance" of the tissues of the patient. It is obvious that if this be correct fibroid tuberculosis, *under ordinary* conditions, will be characterised by comparatively little rise of temperature, though as the result of a dose of tuberculin injected *artificially it may* be possible to set up a well-marked reaction. The same holds good of those lesions in which the caseous masses, surrounded by a fibrous capsule, are cut off or isolated from the surrounding tissues. Only when there is some *disturbance of the fibrous tissue, some acute inflammatory* process, some lysis of the bacilli present, some violent exercise inducing absorption of the caseous tuberculous material and the products of bacteriolytic action and auto-inoculation of the patient is any marked rise likely to occur. Moreover, as soon *as the tuberculous* focus is emptied of its degenerated content pyrexia becomes less marked—there is less auto-inoculation reaction. In the somewhat rapidly progressing caseous tuberculosis where the tuberculous process extends beyond a quiescent or *fibrous lesion and* where, in addition to the interstitial tuberculous process, there is a rapidly extending catarrhal pneumonic tuberculosis, the process of auto-inoculation goes on much *more rapidly and completely, giving rise to* severe constitutional changes, *amongst* which continued pyrexia during the working hours of the day is a marked feature, varying according to the extent of the lesion (the amount of "tuberculin" available), the readiness with which the tuberculin may escape from the *caseating lesion, and the activity* and extent of the factors—work, movement, &c.—concerned in the diffusion of the "tuberculin." That tuberculin alone is capable of exciting a rise of temperature in a tuberculous patient appears to be beyond question. The *heat-regulating centres then* become unstable, overworked, or irritable, whilst when the products of septic or other bacteria act as adjuvant factors—and this occurs specially in the later stages of the disease—the temperature variations undoubtedly become exaggerated, and, very frequently, considerably altered in general character. For the present, however, we confine our observations to what may *be termed* a "*pure tuberculin reaction.*"

Quasi-continuous temperature records of the cases now under consideration have been made over a period of eight years, but most of them have been made on patients treated at *Papworth*. Some of the patients studied have succumbed to tuberculosis, others are still at work, but in all the conditions have been carefully *noted*. *Some of the contacts of these* cases serve as controls and are still under observation, and the earlier deductions made from a study of the various temperature charts are thus capable of verification by subsequent experience.

The "Plateau" Curve is Pathognomonic of Tubercle.

The most important of our observations is that as in tuberculosis in cattle, so in pulmonary tuberculosis of the human subject when the disease is progressive, a continuous temperature chart shows *a* characteristic curve—the "plateau" already described[28]—a curve which can always be reproduced in the tuberculous subject by *over-exercise* or by the injection of a suitable dose of tuberculin. Further, on reference to the *notes of the cases here recorded it will be found that in* all the doubtful cases in which the patient ultimately did badly this "plateau" temperature curve developed even *during the* early stages of the disease. This plateau, as we have seen, is characterised by a more or less rapid rise of temperature, 99° or more, a temperature which remains above 99° for a period of from 8 to 12 hours, the plateau commencing usually, though not *invariably, about* 2 P.M., *and* extending until 10, 11, 12 o'clock at night or later, when there is usually a sudden fall, often with, but sometimes without, a "night sweat."

The indication so afforded is so reliable that it may *be accepted as almost pathognomonic* even when other *aids to diagnoses are wanting and a series of curves* taken from a suspect embody information which will almost certainly eliminate doubt as to the diagnosis, whilst in a diagnosed case the "plateau" curve *indicates the need of further treatment*, in that it supplies definite evidence of the activity of the morbid process.

In all the cases in which the plateau is well developed the up and down lines are well accentuated, very slight *physical movement or mental* disturbance causing sudden rises, rest and ingested cold fluids determining equally rapid falls, whilst a restless night with disturbed sleep invariably gives rise to an irregular curve. In tuberculous patients, as in the healthy individual, the *temperature is lowest at a time when sleep* is most profound, and when the various functions appear to be least active. Another important feature is *that as the* disease progresses the plateau becomes more and more extended, and as this occurs there is a tendency for *the summit to move* more and more to the right, that is, to be prolonged into the morning hours; consequently in very advanced *stages of the disease* this may become so marked a feature that we have practically an "inverse" temperature.

In all the advanced cases and in some of those progressing but not yet advanced, "peaks" appear at intervals along the plateau, and *for short periods the* temperature may run to 102°, 103°, or even 104°—1°, 2°, *or 3° above the general level of the plateau.*

The evidence of auto-tuberculinisation is invariably most marked at the times at which the various functions of the body are *most active*, the night sweats ushering in the rapid fall of temperature at the end of the plateau, in certain cases, *to subnormal*. We look upon a sudden fall as associated not only with the night sweat but with the exhaustion of the patient induced by *the tuberculin reaction*, a process quite distinct from the disappearance of the pyrexia on the formation of a well-defined cavity, *the result of softening* and the evacuation of the caseous material—the tuberculinising centre. As the disease advances the variation *between evening* and morning temperature up to 103° and down to 96° or lower appears to be nothing but an exaggeration *of the tuberculin* reactions from auto-inoculation, as we find that in cases in which the tuberculin plateau is well developed *the fall of temperature* is sudden during the night and the point reached is extremely low; consequently the diurnal variations as measured by the ordinary clinical thermometer must be great. It is only towards the end that the increase of the pyrexia becomes continuous, the highest point sometimes being separated from the lowest by a single degree only.

---

[28] Loc. cit., pp. 435, et seq.

Conclusion.

We maintain that the quasi-continuous temperature record of a reaction is a valuable diagnostic indication as to (1) the tuberculous nature of the disease; (2) the activity of the process; and (3) the prognosis. As to the type of the disease, however, "acute miliary," "caseous pneumonic," "chronic fibroid," &c., though, as seen above, the temperature may give some indication, the physician will find that physical signs afford considerably more specific information.

The temperature indications as to the resistance, or lack of resistance of the tissues of the patient are of extreme interest, especially in regard to prognosis. Instability of the temperature affords evidence of (*a*) a high toxic absorption; (*b*) ready reaction of the tissues to the toxic stimulation; and (*c*) marked interference with the rest function of the patient. A restless night is reflected in the temperature curve, and it appears that the inverse temperature is, to a large extent, the result of a continued auto-inoculation, during which a minimum stimulus produces a maximum reaction both as to amount and duration.

In the night sweats we have evidence of some interference with the autonomic nerve centres, leading to dilatation of the surface blood-vessels, great radiation of heat from the cutaneous surface, and a rapid lowering of the general temperature.

At the outset of our observations we thought it well to compare the rectal temperatures with a series of temperatures taken in the mouth with the ordinary mercury clinical thermometer, but, as will be seen from the figures marked on the charts, these temperatures bear little relation to the rectal temperatures. In the advanced stages of the disease some information could certainly be obtained from these readings, but we are now satisfied that they give little indication of the extent or progress of the disease or, in its earlier stages, of its presence.

To the Medical Research Council we are indebted for a grant to enable us to continue this investigation, and we wish here to tender our hearty thanks for the assistance so afforded.

HELIOTHERAPY IN THE HIGH ALPS.

BY A. ROLLIER, M.D.,

MEDICAL DIRECTOR OF THE HELIOTHERAPEUTIC INSTITUTIONS AT LEYSIN, SWITZERLAND.

THE therapeutic action of the sun has for a long time been attributed to the invisible rays of the spectrum, especially to the ultra-violet, of which the bactericidal action has been demonstrated by a number of eminent bacteriologists (Arloing, Luclos, Tyndall, and others). Experiment has also shown that it is to the ultra-violet rays again that the production of cutaneous pigment must be attributed; this is considered a defensive reaction, preventing chemically active rays from penetrating deeply into the tissues. The ultra-violet rays are absorbed by the melanin of the epidermis, by the lipochrome of the adipose tissue, and by that of the blood plasma. Absorption by lipochrome can be proved by the spectroscope. The amount of energy derived from the rays absorbed, and the use made of it by the body, form interesting subjects for speculation, but lack of experimental evidence makes it impossible for any definite conclusions to be formed. Reference should, however, be made to the experiments of Dreyer, which showed that certain fluorescent substances, such as eosin and erythrosin, have the power of transforming rays of short wave-length into those of longer wave-length. In a paper published in 1908[1] Dr. Rosselet and I drew attention to the indications for attributing the same power to cutaneous pigment. Inability to find a solvent capable of dissolving melanin made definite proof of this hypothesis impossible.

The experiments of Weissner, demonstrating the powerful bactericidal action of the infra-red rays, show that it is not only the ultra-violet which are of therapeutic importance. On account of their greater wave-length and amplitude, these infra-red rays give out a considerable amount of heat when they impinge on the surface of the body, and in comparison with the superficial action of the ultra-violet rays they have quite remarkable powers of penetration. Malgat claims to have demonstrated their passage through hand, arm, and even thorax, but his experimental methods, especially with regard to the thorax, were not very satisfactory. On account of their heat the infra-red rays are also active in vaso-dilatation, which favours phagocytosis, and tends to relieve the congestion of the internal organs. Although it cannot be denied that excellent therapeutic results have been obtained with artificial light, especially with ultra-violet rays produced by the mercury vapour lamp, I am strongly of opinion that up to the present science has not yet invented an adequate substitute for sunlight; on this point I have the support of Finsen himself, who admitted that the ideal treatment for lupus was heliotherapy at a high altitude. In view of the fact that in nature we so frequently meet with organic substances or living cells which are affected only by rays of wave-lengths varying between definite and comparatively narrow limits, it seems not improbable that similar conditions apply to the human body, and that certain rays act on one type of cell and quite different ones on another. Were this the case, the advantages found in practice from the use of the total solar radiations would receive an easy explanation.

Climate.

Heliotherapy may be carried out in any place where the sun shines; but different points on the earth's surface show great variation in the quality of the sunlight which reaches them, and also in other factors affecting the cure.

To reach sea-level the sun's rays have to pass through the whole thickness of the atmosphere; over all our big cities the latter is rich in mists, dust, and micro-organisms of every kind, which absorb both heat and light-rays in a proportion sometimes as high as 95 per cent. This absorption not only deprives the patient of a large number of useful rays, but by heating the air may give the sun-bath a relaxing instead of a stimulating effect. At high altitudes, on the contrary, the air is transparent, free from solid particles, and easily traversed by the sun's rays, which pass through without absorption, and warm and invigorate the body of the patient while leaving the air cool and fresh. For this reason a much greater intensity of direct sunlight can be borne at high altitudes, and heliotherapy may be practised in every month of the year.

The Skin.

I feel it necessary at this point to make a plea for that much ill-used organ, the skin. We Europeans are apt to regard with a complacent superiority the way in which less enlightened races maltreat their bodies (e.g., the feet of Chinese women), but we ourselves would do well to imitate more closely certain less cultivated races with regard to the treatment of the skin. The paramount importance of this organ cannot fail to be realised when we consider the complexity of its functions.

It is, in the first place, an admirable protection against pathogenic organisms; it is the seat of cutaneous sensation, and an excretory organ second only in importance to the kidney; it is very closely concerned in the delicate mechanism regulating the temperature of the body; and finally, as a very vascular layer it plays an important part in the nutrition of the underlying tissues. By covering the body with clothes every one of these functions is interfered with to a greater or lesser extent. I have frequently noticed that the resistance of a patient against disease is closely proportional to his degree of pigmentation, and pigmentation does not take place under clothes. It is a well-known fact that cutaneous sensation is much more delicate in the uncovered regions of the body, and it is equally obvious that clothes, by preventing free evaporation, interfere with the excretory functions of the skin. The contrast between the tolerance to wide ranges of temperature shown by the face and hands and the extreme sensitiveness of the rest of the body gives some idea of the extent to which disuse atrophy of the heat-regulating mechanism has taken place. The increased vascularity of the skin produced by the sun's rays causes considerable thickening of the organ itself, and also appears to result in an increase of the adipose tissue beneath the skin. The splendid muscular development usual with heliotherapy, even in patients confined entirely to bed, is more difficult to explain; direct stimulation (possibly of electrical nature) by certain solar radiations may perhaps be involved, as vascular changes alone would hardly seem a sufficient explanation. When these facts are borne in mind, the frequently quite remarkable results obtained by heliotherapy are to a large extent explained, as it is only to be expected that the return of these numerous and important functions to the skin would have a most beneficial effect on the general health.

[1] Sur le rôle du pigment épidermique et de la chlorophylle. (Bulletin de la Société vaudoise des Sc. Nat., vol. xliv., 1908.)

Action on Pathological Processes.

The secret of the sun's action on pathological processes is that while highly toxic to micro-organisms in general (and to the tubercle bacillus in particular), the solar radiations are not only harmless, but actually beneficial to the cells of higher animals. This specific action of sunlight was of great assistance in the treatment of suppurating war wounds.[2] The sun thus appears to increase the rate of disintegration of cells damaged beyond repair, while stimulating the activity of the undamaged cells. A torpid lesion (such as varicose ulcer) demonstrates particularly well this cicatrising action of the sun. Anæmia and rickets, essentially diseases of deficient sunlight, are similarly amenable to heliotherapeutic treatment.

Surgical Tuberculosis.

It is, however, in tuberculosis, and especially in the surgical varieties (bones, joints, glands, peritoneum, &c.) that the action of the sun is seen to its fullest extent.

It has long been realised that the severity of a tuberculous infection does not depend solely on the severity and extent of the anatomical lesion, but also, and to an even greater degree, on the state of the natural defences of the body; general treatment is therefore tending more and more to replace local interference of a surgical nature. In heliotherapy the results obtained are, in my opinion, at least as much to be attributed to the general as to the local action of the sun's rays, the complementary action of the mountain air being a further primary factor in the cure. The various stages in the reparative processes which heliotherapy causes tuberculous lesions to undergo are best followed by means of X ray plates taken at intervals of a few months. The decalcifying action of the tubercle bacillus is particularly well shown in these plates, but is apt to be rather misleading, as complete disappearance of a bone on the plate does not indicate that it is entirely destroyed. For instance, in hip disease the first plate often shows no signs of either head or neck of the femur or of the acetabular margin; after some months of treatment signs of recalcification appear and vague outlines become evident; these gradually become more definite and may eventually be as sharply defined as on the healthy side. In other patients, in whom the head of the femur has perforated into the pelvis, radiography permits us to follow, in some cases, the formation of a new joint. The first hopeful sign is the reappearance of a bony septum, vague at first in outline, between the head of the femur and the pelvic cavity; this becomes more compact and a new articular space between it and the reappearing head of the femur becomes evident; the new joint formed in this way may give considerable return of articular function in cases where this could hardly have been hoped for. In spinal caries similar changes may be observed, and tuberculous abscesses may be seen to disappear altogether, or, as is more frequently the case with adults, calcification of the residue may take place. It is in tuberculous dactylitis that changes in the calcium content of the bones cause the most striking results; phalanges which have entirely disappeared may be so completely recalcified as to be indistinguishable from the normal bones. The differentiation due to heliotherapy which takes place between irreparably damaged cells and their healthy surroundings is well illustrated by the behaviour of sequestra; sharp demarcation followed by spontaneous elimination is frequently observed.

Technique.

In order that the best results should be obtained from heliotherapy it is necessary that a definite technique should be employed. There are great individual differences in the adaptability of patients to this form of treatment, and in order to avoid excessive and possibly harmful reactions in every case it is necessary that progressive insolation should be carried out cautiously and any symptoms of intolerance taken into account.

Exposure always begins with the feet, the legs, thighs, abdomen, and thorax following in this order with an interval of a varying number of days between each. Only a few minutes' exposure is allowed to each part on the first day of insolation; this amount is gradually increased until at the end of a period of time which varies with each subject—degree of pigmentation and absence of excessive reactions being the criterion—the patient is able to expose the whole body to the sun for several hours daily without any inconvenience either in summer or winter. Secondary infection without free drainage, pulmonary and abdominal tuberculosis, are conditions in which increased caution are necessary. Far from contra-indicating heliotherapy, however, they are greatly benefited by this form of treatment if properly carried out. Plaster apparatus is a great hindrance to heliotherapy and is almost invariably discarded, as not only does it interfere with the local action of the sun on the diseased part, but it also causes muscular atrophy, which is a great disadvantage when return of function begins, and compares most unfavourably with the thick covering of well-developed muscle, which is usual with heliotherapy, and forms an admirable support for a weakened vertebral column or joint. These cumbersome devices of plaster should be replaced by simple arrangements of webbing straps which give complete immobilisation and adequate extension while permitting free access of air and sun. I have no space here to describe in detail the orthopædic technique used for each localisation of the disease, and must refer the reader desirous of further information to my book, "La Cure de Soleil."

The Work Cure.

This most valuable factor in the treatment of tuberculosis was, I believe, first introduced by M. Paterson at *Frimley Sanatorium.*

As an adjunct to heliotherapy its value would be difficult to over-estimate; for in surgical tuberculosis the psychology of the patient is apt to be seriously affected by enforced immobilisation for many months, and mental depression invariably has its counterpart in the physical condition of the patient. Even in serious cases of tuberculosis of the vertebral column, hip or knee, much benefit can be derived from such handicrafts as wood-carving, weaving, basket-making, metal-work, painting on wood, toy-making, &c. Not only does this work cure benefit the patients mentally, but by enabling them to continue earning during their treatment it has in many cases made it possible for patients who would otherwise have left only partially cured owing to financial difficulties to continue treatment until cure was complete.

Prognosis.

Although the prognosis of surgical tuberculosis is exceedingly favourable when the lesion is closed, this can hardly be said to be the case when secondary infection with pyogenic organisms—on which the sun has a much less specific action—has taken place.

Cases of meningitis hardly ever occur, not one per annum, and in unfavourable cases death is almost invariably due to the secondary infection and the resulting amyloid degeneration or cardiac failure of toxæmic origin. Closed cases of pelvic or sacro-iliac tuberculosis invariably progress favourably with heliotherapy; but when secondary infection has once taken place the anatomical structure of these parts makes drainage so difficult and retentions so frequent that the prognosis becomes much more grave. Experience with cases of this type has made me more than ever insistent on the necessity of beginning active heliotherapeutic and altitude treatment as early as possible in all cases of surgical tuberculosis. It has been suggested that heliotherapy is more effective with children than with adults; I have always had a considerable majority of adult patients and have not been able to support this view, except, perhaps, in certain synovial infections of the knee and in genito-urinary tuberculosis.

Giving the results obtained with children and adults in separate columns my statistics since 1914 for osteo-articular tuberculosis only are as follows:—

—	Children.	Adults.	Total.
Cured	681 (86·5%)	1065 (77·2%)	1746 (80·5%)
Improved	51 (6·5%)	191 (13·8%)	242 (11·2%)
Stationary	43 (5·5%)	104 (7·5%)	147 (6·8%)
Worse and deceased	12 (1·5%)	20 (1·5%)	32 (1·5%)
—	787	1380	2167

These results were subjected to a strict radiographic control. Older statistics, up to 1914, dealing with all types

---

CASE 1 (see top row of page illustrations), aged 8½, on ski.

of surgical tuberculosis, gave the following proportions out of 1129 patients (662 adults, 477 children):—

Cured	945 (83·7%)	Stationary	41 (3·6%)
Improved	112 (9·9%)	Deceased	31 (2·8%)

In these statistics, as well as in the preceding, the cases that remained stationary, got worse, or died, are nearly all cases who suffered from secondary infection.

Maintenance of Cure.

No treatment, however rapid its effects, is really good unless it yields permanent results. It is obvious that if recently cured patients return immediately to those conditions of life which fostered the development of their disease a relapse is only to be expected; in every case, therefore, it is advisable that for some years at least the patient should work in suitable surroundings.

For children an open-air school where sun cure can be continued is the ideal half-way house for the convalescent, and the one under my direction has fully justified its existence. With regard to adults, my experience with farm colonies has confirmed my opinion that agricultural work has an admirable effect in consolidating a cure, and I am advocating their widespread establishment.

I have recently been occupied in preparing statistics to illustrate the permanence of cures reached by heliotherapy; unfortunately, the fact that my former patients are scattered all over Europe has greatly interfered with this work, and I regret that the figures are not yet ready for publication. I have already succeeded in obtaining photographs of a large number of patients whose cure was completed 10, 12, or 14 years ago; these, together with previous photographs taken before and after the treatment, were shown at the annual assembly of the "Association suisse contre la Tuberculose" on Nov. 14th, 1920. A few selections from the series are here given.

Prophylaxis.

"Dove non va il sole, va il medico" (where the sun does not go the doctor goes), is an old Italian saying, the truth of which is very evident to all those concerned in the treatment of tuberculosis. We know now that surgical as well as pulmonary tuberculosis is in the great majority of cases secondary to infection of the tracheo-bronchial or mesenteric glands; this usually takes place in childhood and may remain latent for many years, only becoming active when, for some reason, the resistance of the body is lowered. For these delicate or predisposed children I am applying the same treatment as for convalescents. The children have as much fresh air as possible day and night, with plenty of good and simple food, of which fresh farm produce forms a large proportion. School work is reduced to a subsidiary position, its object being merely to keep the mind in discipline; the use of very light folding desks and stools makes it possible for lessons to be held in the fields and the woods, the site being varied according to the heat of the day. In summer the children spend the whole day in bathing kit, and even in winter clothes can often be dispensed with, at all events during rest hours in the solarium. Much attention is given to Swedish drill, as I believe proper expansion of the chest and nose-breathing to be a most useful prophylaxis against a multitude of diseases. The results obtained by this open-air school have been most encouraging, and give reason to believe that in almost every case the disease may be completely eradicated before any manifestations take place, thus avoiding much suffering and expense.

We know that there is no surer way of building up the resistance of the body than life in the open air and sun, yet we are very slow to apply this knowledge to the conditions of our everyday life, and until we do so tuberculosis will continue to exact its heavy toll of victims each year.

DESCRIPTIONS OF ILLUSTRATIONS

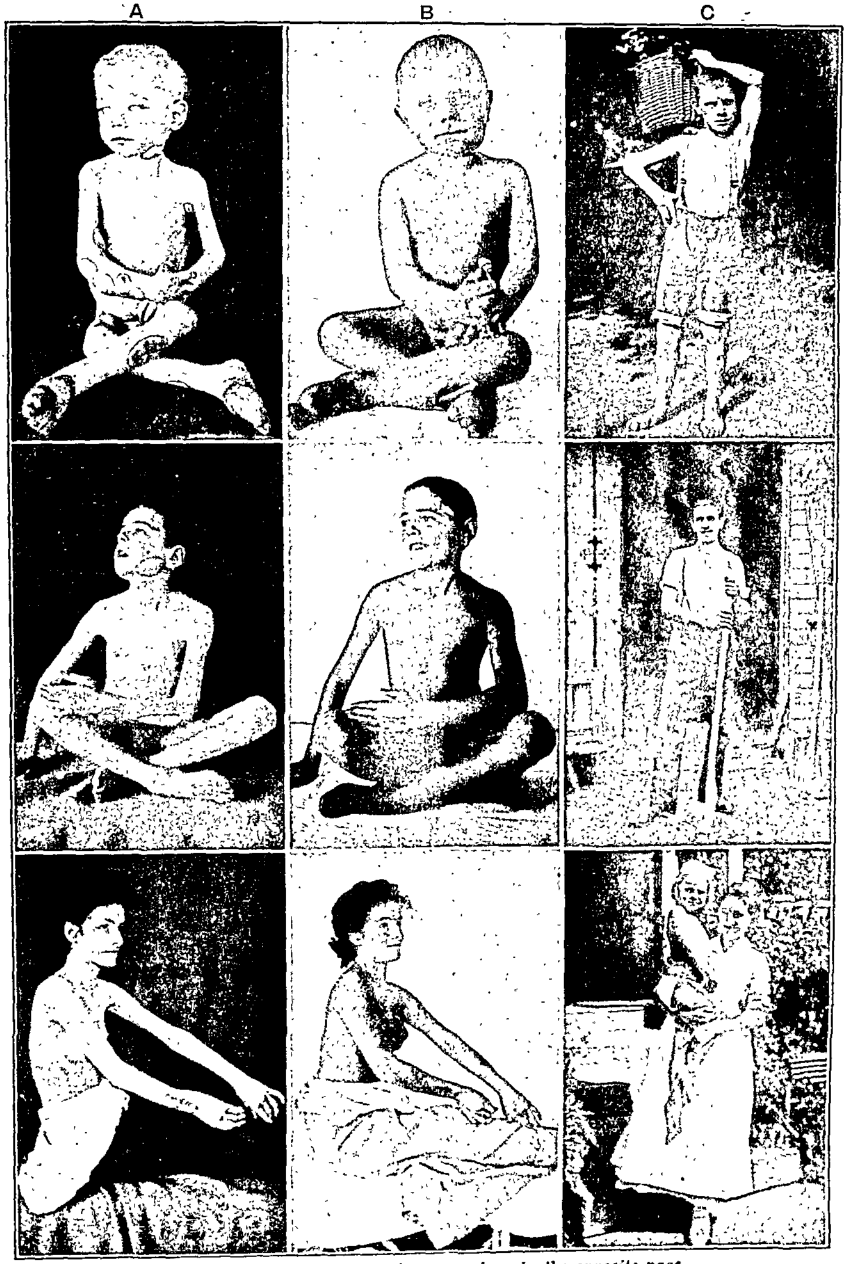
(*see opposite page*).

In each row (A) shows the patient at the beginning of treatment; (B) shows the effects of from six months' to a year's treatment; (C) shows the patient in home surroundings after periods of from 10 to 14 years from the taking of the first photograph.

CASE 1 (top row).—(A) Child, age 4½, arrived with 34 tuberculous foci, osteitis, periosteitis, adenitis, multiple fistulæ, tuberculosis of both feet, right hand, peritonitis, and advanced tuberculosis of left lung. General condition very poor, advanced cachexia, high temperature, and albuminuria. (B) One year later—all tuberculous foci cured and fistulæ closed. General condition completely transformed. (C) At age of 14½; cure completely maintained in spite of the patient having lived throughout the war in Germany, where he underwent considerable privation.

CASE 2 (second row).—(A) Child with 17 tuberculous foci on arrival, osteitis, periostitis, adenitis. One lesion in temporal region had been curetted. Secondary infection, fistulæ; affection of tracheo-bronchial glands and infiltration of right apex. (B) Complete cure six months later. (C) 13½ years after establishment of cure. Wheelwright and agricultural labourer. Did more than a year of military training without a day's illness.

CASE 3 (bottom row).—(A) Case of tenosynovitis and tuberculous arthritis of wrist, recurring after operation. Secondary infection, fistulæ; renal tuberculosis, nephrectomy, tuberculous peritonitis; tuberculosis of right apex, small lupus on right cheek. General condition poor; habitus phthisicus. (B) The same patient one year later. (C) The same patient 13 years after establishment of cure. In good health and very active as a nurse.



Descriptions of these illustrations are given in the opposite page.

THE CHEMICAL ESTIMATION OF GASTRIC FUNCTION

BY THE TEST MEALS OF EWALD AND BOAS.

BY J. H. RYFFEL, B.CH. CAMB., F.I.C.,
CLINICAL CHEMIST, GUY'S HOSPITAL.

MANY test-meals have been employed in the investigation of gastric function, but I propose to consider only the results of the two which have been most generally used—namely, that of Ewald, which consists of tea and toast, and that of Boas, which consists of oatmeal and water. The modified test-meal of Ewald consists of one pint of tea with a little sugar and milk, if desired, and about 2 oz. of toast, given as the first meal in the day, and removed about one hour afterwards. Some observers allow a little butter with the toast, but to omit the butter has the advantage that, if much fat is found in the contents of the stomach after the meal, its presence affords evidence of a considerable degree of gastric delay, as the fat must be a remnant from a previous meal. In removing the meal without the addition of water Senoran's aspirator is a very considerable aid. When obtained, the contents of the stomach are measured and filtered, the solid part being examined for blood, bile-pigment, organisms, and food materials, while the filtrate is subjected to various titrations.

Determination of Acidity.

For determining the acidity different indicators have been proposed. Total acidity is usually determined by titration with caustic soda, using phenolphthalein as indicator. The earliest indicator for free HCl was that of Günzberg. This has been shown to give results comparable with those of physical measurements, but as the test involves evaporation it is not convenient for purposes of titration. Töpfer introduced dimethylaminoazobenzene, which has been widely used, but the region of change for this indicator lies between N/1000 and N/10,000 HCl, and the end-point as ordinarily employed about N/5000 HCl, which is distictly too low in the acid scale for a determination of free HCl.

Although the term "free HCl" is in this connexion a misnomer, the indicator is of great utility, as organic acids produced by the Oppler-Boas bacillus, or by acid streptococci, never attain either in the stomach, or in culture in the presence of sugar, an acidity great enough to affect dimethyl, so that this titration is not affected by organic acids. Rolph proposed to use instead tropeolin 00, which reacts at N/200 HCl, while recently Cole and Adie have urged the use of thymol-blue working to an end-point $= \text{HCl.N} \times 10^{-2{\cdot}6}$, or about N/500. This indicator would leave a large gap between the total acidity and the free HCl, so that it would surely be better to retain dimethyl, and, in addition, adding a suitable indicator to the filtered contents to compare the tint obtained with a series of tubes containing known quantities of free HCl, so as actually to determine the concentration of hydrogen ions present. This procedure would overcome the difficulty that with dimethyl, owing to the presence of buffers in the liquid, a high result by titration does not necessarily denote a high degree of acidity, but it would be necessary to use Boas's test meal to avoid dealing with a pigmented fluid; the procedure would be practically impossible to apply to a blood-stained or bile-stained fluid. B. Moore employed the rate of hydrolysis of methyl acetate to determine the free HCl. The method is sound physically, but somewhat laborious.

Willcox developed the determination of a quantity of a different kind, the "active HCl." This is based on the method originally employed by Prout to demonstrate the presence of free HCl in gastric juice. It is essentially a determination of the loss of chloride on ignition, and includes free HCl and HCl combined with proteins and other volatile bases. Active HCl corresponds closely th the result of the titration of total acidity, unless nic acid be present, when the difference between two measures the organic acid. Graham pointed out that the estimation of mineral, or non-volatile, chloride, which is involved in the estimation of active HCl, was itself of value, as this quantity was notably increased in carcinoma of the stomach and in regurgitation of duodenal contents into the stomach.

Table showing Results obtained by the Method of Willcox and Graham.

—		Grammes per 100 c.cm.				Blood.	Lactic acid.
		Free HCl.	Active HCl.	Acidity as HCl.	Mineral HCl.		
Normal		0·10	0·15	0·15	0·10	–	–
Hyperchlorhydria... ...		0·25	0·36	0·37	0·12	+	–
Carcinoma ventriculi.	1	0	0·0094	0·079	0·315	++	+
	2	0	0·05	0·196	0·27	++	++
	3	0	0·079	0·115	0·14	+	+
	4	0	0·106	0·13	0·24	+	–
	5	0	0·031	0·029	0·117	–	–
	6	0·14	0·24	0·25	0·17	++	–

The table shows results obtained on the lines recommended by Willcox and by Graham—namely, a typical normal result, a typical instance of well-marked hyperchlorhydria with pyloric ulcer, and six examples obtained from proved cases of carcinoma ventriculi. Of these 1, 2, and 3 are instances of pyloric carcinoma in which the presence of blood and lactic acid with absence of free HCl, low active HCl, and high mineral chloride leave no doubt as to the diagnosis; 4 is an instance of carcinoma without obstruction in which the presence of blood, absence of free HCl, active HCl below normal, and high mineral chloride are suggestive of the diagnosis. In 5, as there is no blood and the mineral chloride is not appreciably above normal, there is nothing to distinguish the case from other instances of hyperchlorhydria such as that found in pernicious anæmia; blood, however, was found in a later test-meal and in the fæces. In 6, an instance of carcinoma with HCl above normal, the mineral chloride is high but less than the active HCl. Besides the mineral chloride, the only other point to distinguish from ulcer was that the growth bled freely and that the bleeding did not respond to treatment.

Sources of Error.

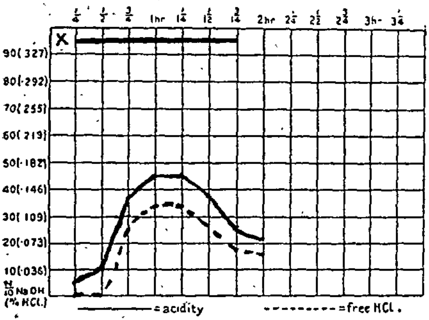
In test-meals of this type there are two principal sources of error: If the stomach empties quickly, as it frequently does in cases of duodenal ulcer, a small amount of material is obtained, which is rich in mucus, poor in toast, and contains HCl less than normal and a high mineral chloride. The remedy is to shorten the time so as to obtain a true sample of the meal. The other source of error is that aspiration is liable to cause some bleeding; there the remedy is to insist on examination of the fæces for blood in every case. If the blood in the test-meal is due to trauma it will not be found in the fæces; moreover, blood may be found in the fæces where it is not appreciable in the gastric contents. In this connexion I may note that a spectroscopic examination of the fæcal extract for acid hæmatin and hæmatoporphyrin, in addition to the ordinary tests for blood, is most desirable, and, when it gives positive results, removes all doubt that the blood found may have been introduced in the diet. Apart from sources of error, the principal difficulty is to distinguish, on the one hand, between carcinoma and ulcer of the body of the stomach, as in the latter the HCl may be relatively low and the mineral chloride somewhat high, and, on the other, between carcinoma and other cases with hypochlorhydria, as the indications obtained from the mineral chloride are not absolutely consistent, being occasionally normal in carcinoma and occasionally high in gastric atrophy.

The Ewald test-meal is notably lacking in two respects: it gives only the roughest indications of the rate at which the stomach empties, and, if the gastric secretion is abnormal in its time relations, entirely misleading figures as to acid may be obtained. These difficulties are obviated by the procedure introduced by Reyfuss and Hawk, in which the patient swallows a narrow tube, by which samples of contents are

CHARTS OF GASTRIC ANALYSIS.

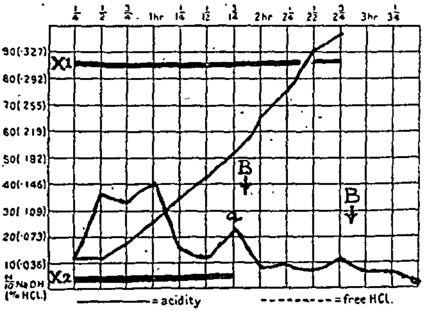
In the charts B = bile, X = starch, Y = sugar, Z = blood.

CHART 1.



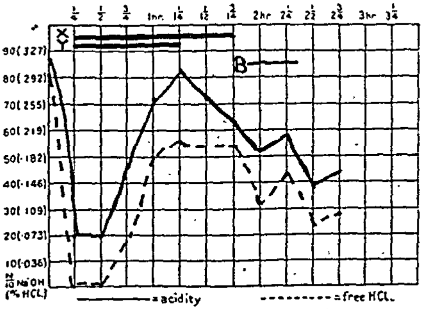
Showing the ordinary normal as given by Crohn and Reiss. In certain apparently normal individuals the acid may be much lower or much higher, and the stomach may empty more quickly. Bennett gives two and a half hours as the normal limit of time for disappearance of the meal. On the whole, the curve is characteristic of the individual, but it is subject to certain influences, of which the most important in practice are discomfort on the part of the patient, nausea, retching, and attempts to vomit.

CHART 2.



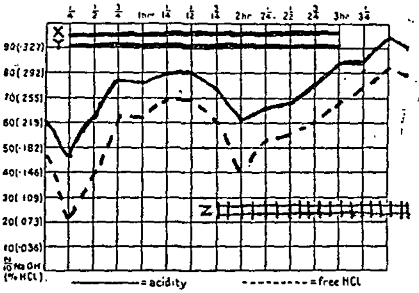
Showing two very different results obtained from the same individual—a case of hysterical vomiting; on the second occasion the patient did not take kindly to the use of the tube.

CHART 3.



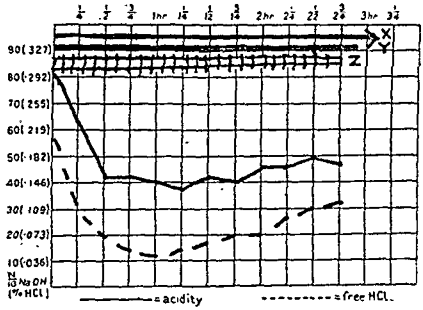
Duodenal ulcer confirmed by operation; showing the highly acid-resting juice and rapid secretion of acid with rapid emptying stomach, which is characteristic of this condition.

CHART 4.



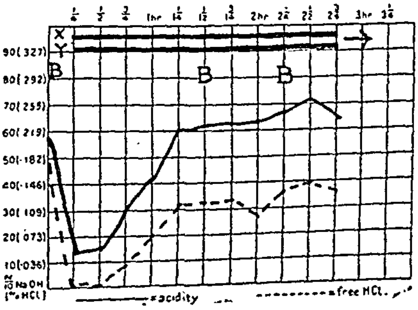
Pyloric ulcer without stenosis.

CHART 5.



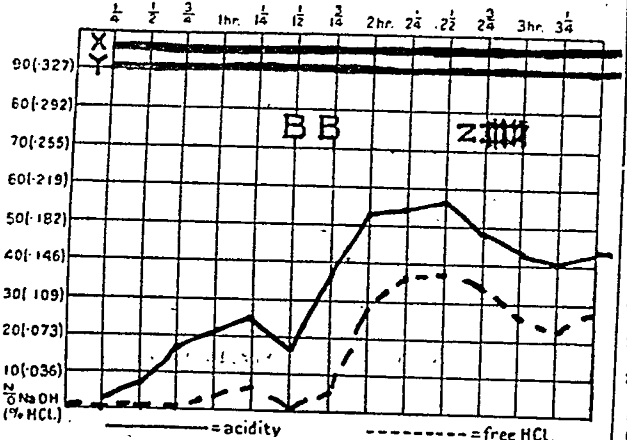
Pyloric ulcer with stenosis, in which the resting juice contained food materials, and the stomach was by no means empty in 2¾ hours.

CHART 6.



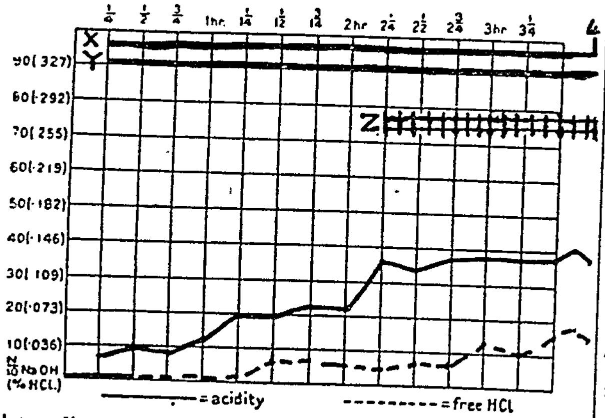
A similar type of curve to 4, except that there was no bleeding but at operation large gall-stones were found in the gall-bladder and no ulcer.

CHART 7.



Gastroptosis, with well-marked gastric delay.

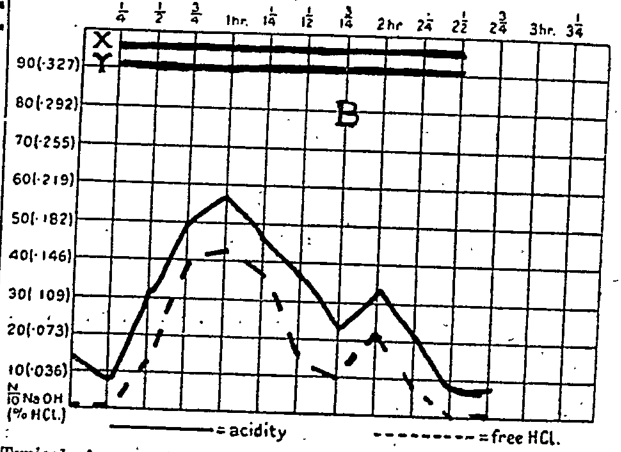
CHART 8.



A case diagnosed as carcinoma of the stomach. Charts 4 to 8 have two features in common: delay in emptying of stomach, and a continued rise in acidity as the meal proceeds. These two features serve to show that the stomach has difficulty in emptying, whether from spasm or stenosis of the pylorus or atony of the stomach with a normal pylorus. Other features serve to make the diagnosis between the different conditions showing this characteristic, thus the essential difference between 8 and 7 is that the former shows blood in the stomach and fæces, while the latter does not, except from trauma. Chart 6 is not characteristic of cases of gall-stones, but suggests that there may occasionally be pyloric spasm in this condition.

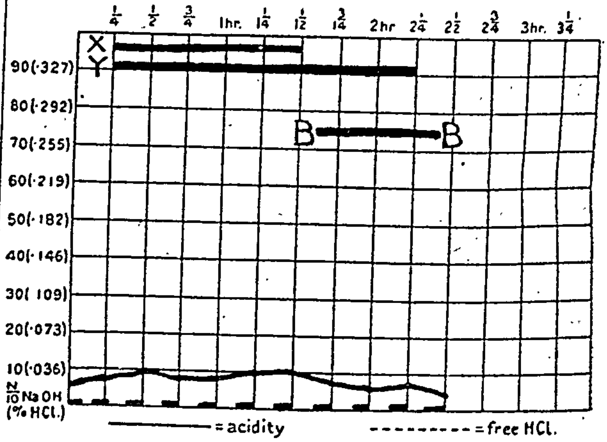
removed before the meal and for every quarter of an hour afterwards, until either the stomach is empty, or a sufficient time has elapsed to show that there is gastric delay, or continued secretion after the meal. The tube used is either Einhorn's duodenal tube, Reyfuss's tube, or Ryle's tube. Einhorn's tube is inclined to block and may cause slight bleeding from trauma. Reyfuss's tube is somewhat difficult to swallow. Ryle's tube is easier to swallow and less liable to block or to cause trauma. The meal used is either that of Ewald or that of Boas. Following Crohn and Reiss, we have used a modified Boas meal consisting of two tablespoons of oatmeal mixed with a quart of water, boiled down to one pint, strained through muslin, and given warm with salt to taste. The samples taken are between 5 and 10 c.cm. They are titrated with dimethyl and phenolphthalein indicators and examined for blood, bile, starch, and sugar. Disappearance of the starch is taken ordinarily as evidence that the meal has entirely left the stomach, but some of the starch is converted to maltose by the ptyalin of the saliva. If the acidity of the gastric contents rises sufficiently the action of the ptyalin is arrested, but if the acidity be low the action of the ptyalin proceeds, and sugar may [illegible] longer than starch. In this case disappearance [illegible] is the end-point. Results of the examination [illegible] expressed as Charts 1 to 10.

CHART 9.



Typical of cases of ulcer of the body of the stomach. Except for evidence of bleeding, which in this case was obtained from the fæces but not from the stomach, there is no chemical evidence of ulcer.

CHART 10.



Typical of marked lack of acid. In this case blood was present in the fæces and at autopsy a carcinoma of the stomach was found, but there is nothing in the chart to distinguish it from one of achylia gastrica.

Conclusion.

In conclusion, one may say that the fractional test meal gives results that are of great interest, but it serves rather for arranging the cases in various groups than for individual diagnoses. The actual diagnosis must be completed from further considerations, and especially by a clinical study of the individual case.

THE DUBLIN HOSPITALS.—The result of the united appeal and fete on behalf of the associated Dublin hospitals was announced a few days ago. Some £35,000 have been realised, of which £15,000 were due directly to the fete. The appeal had aimed at obtaining £100,000. Its comparative failure should prove finally that if the Dublin hospitals are to keep open they must look elsewhere than to voluntary contributions for the means. The sum recently realised can hardly do much more than make up the deficit on a year's—or perhaps a year and a half's—working.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF GUNSHOT WOUND

IN WHICH THE BULLET WAS REMOVED BY MEANS OF THE ŒSOPHAGOSCOPE.

BY G. N. BIGGS, M.B., B.S. DURH.,

LIEUTENANT-COLONEL, R.A.F.M.S.; CONSULTING AURAL SURGEON, EVELINA HOSPITAL AND ROYAL AIR FORCE; SURGEON IN CHARGE, EAR AND THROAT DEPARTMENT, SEAMEN'S HOSPITAL AND ROYAL WATERLOO HOSPITAL.

THE following case is of interest and worthy of record in order to demonstrate for future use the advantages of the method adopted for the removal of a bullet in the neck. The only alternative was a deep dissection.

The patient, a private in the Irish Guards, was under the care of Colonel A. Fullerton, C.B., C.M.G., at that time senior consulting surgeon to the Boulogne Base. He first came under my notice as the result of a gunshot wound; the bullet had entered the right side of his face, penetrated the right antrum, fractured the septum, passed through the hard palate, missed the soft palate, and having entered the posterior wall of the pharynx about 1 inch above the cricoid cartilage had tracked down into the soft tissues, and was shown by X rays to be lying embedded in the muscles about 1½ inches below the cricoid cartilage exactly in the middle line.

Removal of the bullet would have had to be by an extensive dissection in the neck unless another method was found; it was desirable to avoid dissection, for the operation was bound to be followed by infection of the wound, since the bullet was lying in an abscess cavity. The latter fact was proved by the presence of a discharging sinus in the deep pharynx; the opening of this sinus closed from time to time, with the result that a swelling developed in that region and ruptured after a few days, with the free discharge of pus.

I was asked to see the case, and found, on examination with the laryngeal mirror, that there was a small sinus on the posterior wall of the deep pharynx in the middle line, from which protruded some small granulations. At Colonel Fullerton's suggestion I decided to make an attempt to remove the bullet with the œsophagoscope, and had the patient removed to No. 54 London General Hospital.

A general anæsthetic was administered and an œsophageal tube passed down until the opening of the sinus was reached; with great difficulty this sinus was enlarged and the tube passed down it until the bullet could be easily seen. This operation was a long and tedious one owing to the free oozing of blood from the granulations lining the wall of the sinus. The bullet was seized with forceps, and the tube, forceps and bullet slowly withdrawn; unfortunately, just as I was removing the instrument and the bullet the patient coughed violently, the smooth bullet slipped out of the forceps and was swallowed by the patient, but was passed per rectum four days later. The nasal opening of the antrum was enlarged under the same anæsthetic to allow of free drainage and portions of necrotic septal cartilage were also removed.

The patient made an uninterrupted recovery and was evacuated to England about three weeks later; in addition to the condition described he had also a gunshot wound in the right forearm, with a bad compound fracture of the radius and ulna.

I should like to express my thanks to Colonel Fullerton for referring the case to me, and to Captain A. T. Swan for the excellent way he administered the anæsthetic in what proved to be a long and difficult case.

A NOTE ON

PERIARTICULAR ABSCESS AFTER SCARLET FEVER.

BY BERNARD E. MYERS, C.M.G., M.D. EDIN., M.R.C.P. LOND.,

PHYSICIAN TO OUT-PATIENTS, ROYAL WATERLOO HOSPITAL FOR CHILDREN AND WOMEN.

THE following case was observed at the Royal Waterloo Hospital, and is of sufficient interest to be recorded.

P. R., a female, aged 5 years, was admitted to hospital on Jan. 11th last suffering from a distinctly swollen right ankle, which was very tender and painful. The swelling extended to the knee; pain was felt all over this region and in the right hip. The child was pale and looked extremely ill; temperature on admission 99·6° F., pulse 130, and respirations 27; the urine showed a slight trace of albumin, but was otherwise normal.

The history showed that seven weeks previously she had been taken ill with scarlet fever and admitted to a special hospital for treatment. Nothing of importance was noted except a slight albuminuria, and also four weeks after admission a rash developed which was alleged to be chicken-pox. Shortly after this occurred the patient manifested pain in the right ankle, which became steadily more swollen and painful. She had suffered from whooping-cough a year previously and had continued to cough, more or less, since then.

Upon examination of the child, who looked distinctly toxic, the condition of the ankle and leg was as described above, the former being very swollen, red, and exquisitely tender and painful. Pitting was observed over the leg, and fluctuation was felt over the lower part of the fibula. A few râles were heard in the lungs. The albumin noted upon admission soon disappeared and did not return.

It was decided to open up the area of fluctuation and this was done by Mr. J. R. M. Whigham within two hours of admission. From 2 to 3 ounces of pus and blood were evacuated from around the anterior and external surfaces of the joint capsules. It was noted by the surgeon that the subjacent bone and ankle-joint were red and appeared to be involved. It was decided, however, to await developments for from 24 to 48 hours before opening into the joint cavity. The temperature falling at once and the swelling, pain, and tenderness greatly subsiding it was deemed inadvisable to do anything further. In short, the patient made an uninterrupted recovery and left the hospital on Feb. 7th looking really well and able to walk without pain. The pus grew *Streptococcus longus.* The chicken-pox (?) rash, which was still present on admission, had the appearance of a streptococcal rash, and was not chicken-pox.

The interest in this case is the periarthritis and septic rash occurring about five weeks after the onset of scarlet fever and the evident non-involvement of the ankle-joint in the septic process. The question occurs; Was the scarlet fever responsible for the above-mentioned condition? It would be of great interest to hear of others who have had experience of similar cases.

A CASE OF

DOUBLE DORSAL TRAUMATIC DISLOCATION OF THE HIP.

BY ALAN RANDLE, M.C., M.D. LOND.,

ASSISTANT MEDICAL OFFICER, BERMONDSEY HOSPITAL.

ALTHOUGH the mention of a double traumatic dislocation of the hip conjures up visions of patients very seriously mangled and shocked, yet the record of the following case will show that, given the most favourable causative factors, such injury may be productive of little pain or shock and may necessitate only a short absence from a wage-earning existence.

William A——, aged 44, was admitted to Bermondsey Hospital on Nov. 8th, 1920, with a history of accident. He was working near a concreted pit about 22 feet deep, used for storage of coal at a gas works. The pit was practically empty and there was only a little loose slack coal lying at the bottom. A truck being pushed along hit him in the back and he fell into the pit, turning a complete somersault and landing in a stooping position on both feet with his legs slightly apart; after which he pitched forward on to hands and forehead. Hence the heads of the femora were subjected to a force consisting of the weight of the trunk, increasing with every yard fallen, and to my mind also increased by the somersault turned in mid-air, which would give an action like swinging a hammer. The loose coal acted as a shock absorber, and the stooping position favoured a dislocation. The man was raised from the pit on a stretcher with ropes tied to the four corners—a matter evidently requiring very careful supervision—and was brought straight to the hospital.

The patient was suffering very little from shock; there was a small cut on the forehead and considerable bruising of the right foot. I shall not forget the appearance of his lower limbs when the bedclothes were turned up. The inner borders of the patellæ were touching, and the feet were rotated inwards strongly. The thighs would flex slightly, but in an inward as much as a forward direction. On the dorsum of the ilium each side could be felt a hard rounded tender lump. X ray screening showed double dorsal dislocation of the hip, and with considerable difficulty I managed to get a photograph of the two hip-joints on the one plate. In view of the extreme rarity of the injury I was determined to obtain lasting evidence, and the plate[1] is now in the possession of the Museum of the Royal College of Surgeons of England. The os calcis was found to be fractured also, a piece having apparently been torn off by a sudden strain on the long plantar ligament. Under ether anæsthesia reduction of the dislocations was very easily effected by flexion, slight internal rotation, circumduction and external rotation, and finally extension. At the end of the circumduction and external rotation on each side reduction was felt to take place, and neither took longer than half a minute. Slight traction was made by hooking the right arm of the operator under the flexed knee of the patient, and counter extension was provided by an assistant pressing with the hands on the anterior parts of the crests of the ilia. The joints were rested for three days after reduction, and then massage and passive movements were commenced. The right foot was put up in plaster and the patient was allowed to take his discharge on crutches three weeks after admission.

On referring to the literature on the subject I find that the injury has been recorded about 30 times, the nearest description to the accident above recorded being a case of the late Mr. A. E. Barker's. The dislocation is practically always of a mixed type, and this is the only instance I can find of the double dorsal variety.

I am obliged to the chief medical officer, Mr. R. C. Harkness, for permission to publish the case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED MEETING OF CLINICAL, MEDICAL, AND SURGICAL SECTIONS.

GRAVES'S DISEASE: ITS MEDICAL AND SURGICAL TREATMENT.

THE adjourned discussion on this subject was concluded on March 11th, Sir ANTHONY BOWLBY, President of the Clinical Section, being in the chair. Previous reports of the discussions appeared in THE LANCET of Feb. 19th (p. 379) and March 5th (p. 486).

Influence of Operative Measures on Mortality.

MR. C. A. JOLL said that reference had been made to the views of Lieut.-Col. R. McCarrison and others that Graves's disease was due to intestinal stasis or some obscure sepsis. The evidence for this conception of the ætiology of exophthalmic goitre was extremely meagre and unsatisfactory. He had sought carefully among his own patients for septic foci, and had obtained the help of his colleagues in investigating those areas which were in the province of the special departments, and had arrived at the conclusion that there was no ground for believing that Graves's disease was caused by intestinal or any other type of septic absorption. In attempting to estimate the mortality of Graves's disease statistics were quite valueless unless we rigidly excluded all those forms of hyperthyroidism which were not associated with the histological change so typically seen in Graves's disease. Nothing had more tended to obscure the truth than the attempt to group all forms of hyperthyroidism together by introducing such terms as "false Graves's disease" or "formes frustes," &c. No disease had a more definite clinical and histological picture than Graves's disease, and it was very seldom that one had any real difficulty in referring a given case to its proper group, yet he was constantly seeing patients whose case had been diagnosed as Graves's disease and who had been treated for months by rest, X rays, &c., but who were really suffering from encapsuled tumours in the thyroid gland which should have been removed without delay. In true Graves's disease the danger of the operation and the degree of benefit likely to follow depended very largely upon the length of time during which the disease had been present. No surgeon who had had an extensive experience of this work would deny that absolute cures were not to be expected if those toxic changes in the various viscera, which were so well known to occur in the later stages of the disease, were already advanced. On the other hand, he had found that complete cure in the most rigid sense was possible if the operation was done sufficiently early and an adequate amount of the gland removed. He was convinced that if every case of Graves's disease were treated surgically on sufficiently radical lines within three to six months of the onset of the disease the mortality would fall to a negligible figure and cure would be absolute. Unfortunately, at present we did not always see these patients at this early stage, and therefore special precautions were necessary to determine whether an operation could be undertaken with reasonable safely, and further, what type of intervention was wise. He entirely agreed with those who advised a period of rest in bed before the operation, and this might be as much as six months or as little as a week. He was sure that local anæsthesia was not the panacea for operations in Graves's disease. He used it, however, where the patient preferred it, and he employed it in the presence of advanced myocardial disease, but the plea that its use was a dominating factor in reducing mortality could not be maintained, since the results under light open ether in skilled hands were quite as good as those claimed by the advocates of local anæsthesia. The latter, too, was often unsatisfactory.

Treatment by Ligation of Thyroid Arteries.

Very little had been said during the discussion on ligation of the thyroid arteries as a method of treatment. He was a convinced advocate of the ligation of the superior thyroid arteries in very mild cases, which he had seen cured by this method of treatment, and as a preliminary step in grave and advanced cases. The operation was simple and was very suitable for local anæsthesia; a striking degree of improvement often followed. It was generally necessary to resect a part of the gland three to six months later, and such could be done at this stage with less risk than would have been involved in immediate resection. He had only once injected boiling water into the gland, as advocated by Porter. The patient had been operated on elsewhere before and apparently the operation had had to be abandoned owing to hæmorrhage. When he attempted to expose the gland he found that it had become so bound up with the muscles that no plane of cleavage could be found, and he therefore adopted Porter's method as a pis-aller. He was surprised to hear a few months ago from the patient that she was perfectly well. It was to the gentle handling of the gland that he would ascribe the improvement in the statistics at certain clinics. It had been suggested that local anæsthesia helped in this, but it should be recognised that to avoid hæmorrhage was the essential point in this class of surgery, and that this could only be obtained by absolute gentleness, and that the type of anæsthesia had nothing to do with the delicacy of the surgeon's manipulations. The amount of gland to be removed could not always be decided before the operation, as it might be necessary to modify one's plans as the operation proceeded, but he set out, as a rule, to excise three-quarters to four-fifths of the whole gland. Hemithyroidectomy would not cure Graves's disease, though it would generally improve the patient's condition. He was unable to understand those who claimed that it was necessary to remove every scrap of gland tissue in the neighbourhood of the recurrent nerve. If a small portion of the gland were left in this situation cases of recurrent nerve paralysis did not occur, and he understood that the incidence of this disastrous complication was very high where this precaution was not adopted. He had often examined this little piece of gland during secondary operations for the removal of a further portion of gland, and in no case had he seen any evidence of its hypertrophy. The solution of the problem of the treatment of this disease seemed to him to lie in the direction of earlier operation, more extensive resection, and avoidance of hæmorrhage during the operation.

The Present Deadlock.

DR. C. M. WILSON said that there had been a disquieting similarity between this debate and that of 1912. For the most part it was necessary to refer to the date at the top of the page to assign this or that speech to its proper period. Small advances in surgical technique had certainly occurred, and a field that was then the province of a few surgeons was now tilled by many. But in the main a decade had gone without bringing final answers to questions which vexed them then. And while they were marking time they had remained divided into two camps, and not only were the two camps unable to convince each other, but they had not found it possible to present their facts in such a manner that those who belonged to neither could sit in judgment between them. And this was the position not with regard to some difficult and intricate problem of causation, but about the actual results of treatment. What was the secret of this confusion? Was it not because the terms used to describe the condition of a case or group of cases either before or after operation did not succeed in conveying to others the type of case they had in mind? They were in doubt as to what was included under the term Graves's disease and what was excluded. And even when they knew that they were baffled by what was meant by mild, moderately severe, and severe cases. They needed standards. The rational way of ending this state of affairs, if it could be ended, was to express in figures the degree of severity of a case of Graves's disease at any one time, so that all might know the type of case described and be in a position to compare accurately the results of different methods of treatment. It was these considerations, he said, that had led him nearly a year ago to check his clinical observations by measurements of basal metabolism by a modification of the method in use at the Mayo Clinic. This method possessed the advantage that it was admittedly more accurate, and the apparatus more portable, than Benedict's instrument, which, however, had the advantage that it did not require the technique of gas analysis; but he could not enter here into the respective merits of the two different methods of obtaining measurements of the basal metabolic rate. The point was that mathematical measurements could be made by either method of the toxicity of a case of Graves's disease at any one time. These measurements would, he hoped, provide the missing link between the worker and the reader of his printed results. For example, if a case was admitted to hospital with a metabolic rate of 70 per cent. above normal, and this rate was brought down by treatment to 35 per cent., those figures conveyed to others the exact toxicity of the case before treatment and the measure of success achieved. But if, on the other hand, a case which they would now label moderately severe became after treatment a so-called mild case of Graves's disease, no one except those in charge of the patient was really much the wiser.

The Importance of Early Diagnosis.

But these measurements were not only valuable in the selection of the type of treatment, and in following its results as they watched a case of diabetes by estimations of the percentage of the urinary sugar. They were particularly helpful in early diagnosis, of which they had heard too little in that debate. At the present time if unusually favourable results were reported in the treatment of Graves's disease they were met with the criticism that those cases were not Graves's disease at all, because they lacked this or that sign of the complete classical picture, till they were led to question whether this disease had a youth at all, or whether it sprang into being fully formed, like Pallas Athene from the brain of Zeus. The term pulmonary tuberculosis was not confined to cases with cavity formation, and it was no more rational to restrict the name of Graves's disease to a late and intractable stage of the malady. Basal metabolic measurements would provide an incentive to the early treatment of this disease by carrying assurance to the physician that there was actual over-activity of the thyroid, and by convincing him that at such a stage the over-activity could be rapidly reduced to normal limits. They might therefore look for a time when severe and moderately severe cases, around the treatment of which that discussion had so largely hinged, would become clinical curiosities. Pending that time they must evolve some rational procedure in the selection of the line of treatment of such cases. The type of patient to which he was referring generally improved with rest in bed. The metabolic rate fell, for example, from 60 per cent. above normal to 35 per cent., but in many cases after a variable period no further fall occurred, the basal metabolic rate remaining stationary. There were then two alternatives—to trust to time in the faith of Sir William Hale-White that it would prove a reliable ally, and that meanwhile no great harm would befall the patient or the patient's tissues, or, on the other hand, to seek by surgery or X rays to reduce further the basal metabolic figure to normal. It was the choice between these two alternatives that was the difficulty. It might be profitable to consider certain factors that appeared to be delaying the solution of the problem.

The Rôle of the Physician in Graves's Disease.

Primarily, as he had already said, the lack of standards impeded them, but the solution was not brought nearer by a certain lack of detachment very noticeable in that discussion. He would enter a plea that the rôle of the physician in Graves's disease was not as the advocate of this or that method of treatment, but that he should speak as from the bench and with a like authority. There were too many advocates. Some speakers, for example, had contended that the desired result in that disease was more certainly and more permanently attained by operation than by any other means. This was a comparative claim. It implied that the surgeon either had personal and prolonged experience of these other methods or, in default, that he had access to published statistics with which he could compare his own results. But, as they knew, no such data existed. Without such intimate experience of alternative measures those surgeons' results had only the value of uncontrolled experiments. Then there were other speakers who had never seen any improvement from X rays. He would invite them to check their clinical observations by metabolic measurements. They would find that when rest had done all that it could do in many cases X rays would effect a further fall, often to normal. In America, such careful workers as Means and Aub affirmed that when the cases were followed for several years there was very little to choose between the end results of surgery and X rays. He could not escape the feeling that when the same time and thought had been given to working out the dosage and other details of technique as had been devoted to elaborating surgical methods, a more favourable verdict would be passed.

Finally, there was the physician who was averse to surgical interference in any circumstances whatever, on the ground that operation was both unsafe and unnecessary. Such a view, though apparently at variance with the clinical experience of most, had not been finally dismissed, because the criticism directed against it had been vague and ineffective. Surgeons brought to these meetings patients and photographs of patients to prove that thyroid over-activity could be controlled by operation. But that was not the point. The immediate benefits of surgery were not in question; they were rather concerned with the permanency of such results and with the necessity of operation. The case against the surgeon was that operation was unsafe and that it was unnecessary. The risk might be immediate or remote. But if the results of surgery were all that had been claimed, he confessed that he was not greatly perturbed by a 5 per cent. mortality after operation. Those who were had been more fortunate in the results of conservative treatment than he could claim to have been. He, however, was much more concerned with the more remote danger of hypothyroidism. The more they worked in this field the more they came to question not how much of the gland they might safely remove, but whether, taking a wide view of the thyroid's activities, they dared remove any. On the other hand, certain observations in metabolism that he had made demonstrated that this risk of hypothyroidism was not confined to cases treated surgically, but was present after X rays and even after the cure that nature brings about. The point they had to settle was, Did a certain degree of hypothyroidism short of classical myxœdema, but involving a measure of impaired health of which we had taken too little notice in the past, commonly occur, and in that event was surgery the most frequent offender? They might look to basal metabolic measurements to enlighten them on this point. Finally they came to the question, Was operation necessary? and if they were not greatly intimidated by the mortality they would want to know whether Mr. Dunhill's contention that a comparatively large number of patients with this disease suffered grave and permanent damage to their tissues held against Sir William Hale-White's contention that few in fact did so suffer. If they agreed with Mr. Dunhill it was clear that if they shunned surgery altogether many were deprived of the chance of complete recovery. But if they agreed with Sir William Hale-White, then all they stood to lose by adopting conservative measures was a period of invalidism extending perhaps over some years, and the fact that such a period of enforced idleness was for many economically impossible. But even if they agreed with Mr. Dunhill, surely the way to prevent such irreparable damage to tissues lay in early diagnosis, and not with the scalpel. He had made frequent measurements of basal metabolism in 140 cases suffering from hyperthyroidism, the results of which he could not give there. For the moment he was concerned to rescue the method of measuring basal metabolism from the charge that might be formulating in some minds that it was the latest fad in instruments. They needed standards; basal metabolism supplied them. There was a natural reluctance to replace clinical observation by laboratory methods, and the value of any procedure was directly proportional to its simplicity and its general applicability. If records of the pulse and weight of the patient provided what was necessary there would be no place for those measurements, but the pulse, though fairly accurate as a relative gauge, of the patient's condition from day to day, was far from an absolute measure of the toxicity in a particular case; it did not furnish the standard for which they were seeking, while the weight was a singularly erratic index to the patient's progress. The criticism that basal metabolic measurements were too complicated to win a permanent place in the physician's everyday methods came curiously from those who had employed the electrocardiograph in selecting cases for operation. He hoped that these measures would come into general use, so that before the next discussion it would be possible for results to be expressed in a manner understood of all.

Not a Disease of the Thyroid Gland.

Dr. **LEONARD WILLIAMS** contended that cutting operations on the thyroid gland were altogether inadmissible in Graves's disease. Graves's disease was not only not a hyper-thyroidism, but it was not a disease of the thyroid gland at all. There were cases, and many of them were very severe, of Graves's disease in which there was no enlargement of the thyroid. The most outstanding features of the complaint—namely, exophthalmos and cardiac troubles—were due to the implication of other glands. As Maurice, of Lyons, had pointed out, exophthalmos was due to adrenal excess. The cardiac symptoms were due to enlargement of the thymus gland. Graves's disease was due to a toxæmia in which all the members of the endocrine hierarchy were involved. The only way of treating the disease was by discovering the source of the toxin and eliminating it. The toxin was gastro-intestinal in a large percentage of cases, and could only be successfully dealt with by dieting and, if necessary, intestinal antiseptics. The responsibility of the thymus was a point too much neglected. It was enlarged in about 85 per cent. of the cases, and its enlargement caused not only the cardiac symptoms by direct pressure on the base of the heart and the great vessels, but also many of the nervous symptoms by pressure upon the pneumogastric, the sympathetic, the phrenic, and the mental symptoms by interfering with the drainage system from the brain. There was no more justification for the ablation of one lobe of the thyroid in Graves's disease than there would be for the removal of one kidney in diabetes.

Dr. **S. A. K. WILSON** said that he was disappointed that so little had been said of the pathology of a disease, for which so many methods of treatment had been advocated. He was absolutely in agreement that exophthalmic goitre was not a disease of the thyroid gland, but regarded it as a neuro-glandular disease. Changes were well recognised as occurring in the intermediolateral tract of the spinal cord. In seven fatal cases changes had been found in this tract. It was impossible to dissociate the nervous side from the picture of Graves's disease, nor should it be ignored. At present the disease was being treated from without, but he hoped that later it would be treated from within.

X Ray Treatment of the Disease.

Dr. **MARTIN BERRY** spoke of the advantages of X ray treatment which, he said, could be carried out in most cases without taking the patient away from work, without admission to a nursing home or confinement to bed. He recorded a series of cases in which prolonged [illegible] had not been found necessary to effect a cure with X rays. He considered cases as cured when the nervous symptoms disappeared and did not return. The treatment was not contra-indicated, except in cases where there was actual pressure on the trachea. His principle in general had been to administer small doses at short intervals to acute cases, and larger doses at longer intervals to those more chronic. The cases he narrated he said were representative of many others, and were brought forward to show that in some cases it was possible to cure exophthalmic goitre by means of X rays, and that they merited some place in the treatment.

Reply to the Discussion.

Dr. **HECTOR MACKENZIE**, in reply, said that he could not agree that the present discussion showed no advance on that of 1912. The safety of the operative treatment had been enormously increased. Of the cases in which he had coöperated with Mr. Dunhill, none had been lost and all had benefited. The operation was now comparatively safe. He was disappointed in Mr. Joll's view of the importance of local anæsthesia, and that of Mr. J. Berry and Mr. Joll on ligature of the arteries. He had never seen a satisfactory result from ligature, but had met with disaster. It was not worth while tying the vessels, when far better results followed thyroidectomy. He thought that the fact that treatment applied only to the thyroid cured the disease showed also its source. Dr. Florence Stoney's series of cases treated by X rays was a very important contribution to the discussion; in his view X rays or operation formed a part and not the whole of treatment. Estimation of the metabolic rate was no doubt of the highest value, but he was always afraid of any procedure which made treatment more difficult and did not think it would be of permanent utility. Mr. A. J. Walton, he felt, was inclined to underrate the good results of medical treatment; it must be remembered that surgeons only saw the medical failures, as a rule. The outlook for these patients was better than at any previous time. Every effort should be made to cure by medical means, but a considerable number with this alone drifted into invalidism, and for these surgical treatment was especially of value.

Mr. **T. P. DUNHILL**, in reply, doubted the wisdom of including all cases under one term "hyperthyroidism," and said that he made a point of differentiating the various forms as clearly as possible. He had especially not referred to operative technique. In his view ligature of the vessels if necessary was not easy, and if easy was not necessary. He could not accept Mr. J. E. Adams's suggestion of inserting radium into a part of the gland left in situ, and thought that any tinkering with this part was unsafe and materially increased the risk. Nor could he agree with Dr. Leonard Williams that the thymus had a very important influence, since the symptoms disappeared altogether after an operation in which the thymus was not touched. The discussion led to the conclusion that the physician was the person to be in charge of cases of Graves's disease, to direct the various kinds of treatment; if he found that a case was not progressing as it should he should call in a surgeon. With regard to Sir William Hale-White's statistics, he maintained that cases of Graves's disease did not appear in the Registrar-General's reports under their appropriate heading, but as acute mania, renal disease, &c.

SECTION OF LARYNGOLOGY.

A **MEETING** of this section of the Royal Society of Medicine was held on March 4th, Dr. **JOBSON HORNE**, the President, being in the chair.

The late Sir Felix Semon.

The **PRESIDENT** made sympathetic reference to the recent decease of Sir Felix Semon,[1] founder of the old Laryngological Society of London, and for 30 years a distinguished laryngologist in London. He said members of the section could never forget the work which Semon did for laryngology and for the advancement of the specialty. A resolution of condolence with the members of the family was passed.

---

[1] An obituary notice of Sir Felix Semon appeared in THE LANCET of March 12th.

EXHIBITION OF CASES AND SPECIMENS.

New Growth in Bronchus.

Sir J. **DUNDAS-GRANT** showed a middle-aged man from whom he removed a new growth of the left bronchus. He was seen 13 months ago because of cough and shortness of breath of 12 months' duration, the last few days streaks of blood occurring in the expectoration. He had been in a sanatorium, and had wasted somewhat. The dyspnœa was accompanied by stridor, which was mainly inspiratory, and without excursion of the larynx. Tubercle bacilli were never found. Bronchoscopy showed a pale, flapping growth, with fimbriation. The growth was removed by bronchoscopy, and breathing was so much easier that the patient soon left the hospital, with the tracheotomy wound closed. The patient had remained comfortable until a few weeks ago. On direct bronchoscopy a smooth rounded growth was seen, apparently growing from the outer wall. With Killian's forceps only a fragment could be brought away, and as there was now greater comfort the patient was averse to further procedures at present.

The Canfield Operation for Suppuration of Antrum of Highmore.

Sir J. **DUNDAS-GRANT** also showed a patient on whom the Canfield operation had been performed for antral suppuration. In the discussion on the case most of the speakers expressed their preference for the route through the canine fossa.—Mr. **LAWSON WHALE**, however, pointed out an advantage in the Canfield operation in that it gave a better view into the cavity than did the canine fossa route, hence it was better for removing any polypi which might be present.

Cystomata of the Larynx.

The **PRESIDENT** demonstrated, by means of the epidiascope, a number of specimens of cystoma of the larynx. He said cysts of the larynx were not common, but there was much difference of opinion on the point. Sir Morell Mackenzie regarded them as the rarest of the laryngeal tumours. Moure, of Bordeaux, however, considered cysts of the larynx to be the most common form of innocent neoplasm met with in the larynx. He (the President) also showed a retention cyst of the epiglottis, and one of the vocal cord, and a traumatic cyst, which latter developed on the site of a laryngo-fissure operation.—Dr. **IRWIN MOORE** showed a drawing of a cyst of the larynx which was recently discovered accidentally by Professor Shattock, and illustrations of several other cases. He remarked that Cohen stated he had not seen a cyst of the larynx until 1919 in 20 years of out-patient work, and this one originated in the anterior part of the ventricle.—Mr. **HERBERT TILLEY** referred to a very large cyst which he encountered in his practice, and which twice nearly suffocated the patient. The man, at these crises, relieved himself for two or three weeks by putting his finger down and bursting the cyst. Mr. Tilley punctured the cyst and removed most of its wall; but in a few weeks a cyst was again there, as large as ever, and a swelling was present in front of the neck. Mr. W. Trotter thereupon, by a long operation, dissected out the cyst, which included the thyroid bursæ, and was traced into the larynx. This showed that cysts which appeared to be intra-laryngeal might be there only by accident, and have their origin outside the larynx; they might be due to defective fusion of branchial clefts.—Sir W. **MILLIGAN** spoke of two cases of blood cyst on the vocal cords in his practice, both of which he removed.—Dr. J. **DONELAN** mentioned an interesting case of multiple cysts of the larynx which occurred in the practice of Sir Morell Mackenzie in 1889. There were in the patient three cysts in the epiglottis, of fusiform shape, and they were stowed away in the gullet.

Bilateral Paralysis of Internal Tensors.

Mr. **PHILIP FRANKLIN** showed a girl, aged 12, who suddenly lost her voice six months ago. Ever since her fourth year she had had short periods of aphonia. On expiration the arytenoids were seen to meet, the cords being bowed. The mucosa of the nose and pharynx was atrophied. He asked whether the condition was functional or a sequel of nasal infection.—Dr. **DONELAN** did not regard it as true paralysis, but wasting of the internal tensors probably due to myositis the result of over-functioning.—Mr. **WHALE** thought there was posticus paralysis as well as tensor.

Case of Lingual Thyroid.

Dr. G. W. **BADGEROW** showed a woman singer with a lingual thyroid, which was discovered accidentally.—Mr. W. G. **HOWARTH** referred to three similar cases which he had shown at various dates. If these caused trouble and operation was contemplated the operator should first satisfy himself that the patient would have sufficient thyroid tissue left. If the tissue involved was all the thyroid the patient possessed, one could only take away the top of it and treat with the galvano-cautery. He had found 95 cases recorded.

Obstruction of Œsophagus by Foreign Body.

Mr. **SOMERVILLE HASTINGS** related two cases of obstruction of the œsophagus by a foreign body acting as a ball-valve. The first was that of a woman, aged 30, who 13 years ago was found to have constriction of œsophagus, with marked dilatation above it. She improved somewhat and took food better. Eight years ago, however, she had another attack, but improved in six weeks. In September, 1920, the trouble having recurred, the œsophagoscope was passed and a cherry stone was found 11 inches from the incisor teeth; it rested like a ball-valve on a smooth fibrous stricture of the œsophagus. The stone was removed, and swallowing had been normal since, and the patient soon increased in weight. The second case was that of a woman, aged 52, who for several years had had occasional difficulty in swallowing, which manipulation of the neck relieved. Œsophagoscopy revealed, 8 inches from the upper incisor teeth, a large hard pea. Its removal led to disappearance of all symptoms.

MEDICAL SOCIETY OF LONDON.

THE CHEMICAL ESTIMATION OF GASTRIC FUNCTION.

AT a meeting of this society, held on Feb. 28th, with Sir **WILLIAM HALE-WHITE**, the President, in the chair, a discussion on this subject was opened by Mr. J. H. **RYFFEL**, whose paper appears in full in this issue of THE LANCET.

Dr. J. A. **RYLE** briefly described the results of his experience with the fractional test-meal based on personal experiments and employment of the test in out-patient and private practice, and also on an extended investigation of normal subjects in concert with Dr. T. I. Bennett. He claimed that the information afforded by the test, both in respect of gastric motility and gastric chemical function, made it a superior test to the one-hour test-meal of Ewald, and considered it to be the best single method of estimating gastric efficiency. He emphasised the importance of measuring and otherwise studying the resting secretion, and of macroscopic inspections of the serial specimens, and showed charts illustrating the diagnostic features of curves obtained in cases of pyloric stenosis due to ulcer and to growth, of duodenal ulcer and achylia gastrica. With further curves he demonstrated the application of the method in determining the mechanical and chemical efficiency of the operation of gastro-jejunostomy. In summarising, he stated that the method, by combining a 12-hour and a continued test, was most valuable in the diagnosis of pyloric obstruction and its cause; that curves characteristic of duodenal ulcer were very constantly obtained; that in achylia gastrica there was also a characteristic curve; and that in many other unclassified dyspeptic conditions, information of help to the physician from the therapeutic point of view, was frequently obtained by a fractional gastric analysis.

Mr. E. C. **DODDS** said that he had found that measurement of the alveolar CO_2 tension before and after a meal showed a rise in such tension, followed later by a fall; he showed diagrams taken from normal and pathological cases demonstrating this phenomenon, particularly one showing how, in a subject on whom gastrectomy had been performed, the initial rise was absent, but the later fall—which he believed was due to secretion from lower portions of the alimentary tract—was well marked. He said that the evidence that the degree of such changes in alveolar CO_2 tension was quantitative would be brought forward during Dr. Izod Bennett's communication.

Dr. T. IZOD BENNETT began his communication by stating that he did not consider that any really valuable estimate of gastric function could be obtained by any analysis made at one fixed period in the cycle of gastric digestion. He showed diagrams to illustrate how, at the end of one hour, the acidity of many stomachs gave the same reading, whilst at a later period the curves of percentage acidity might become widely divergent in such cases. He then showed the results of the investigation of gastric secretion in normal men made by himself and Dr. Ryle; he drew attention to the four normal types, and demonstrated the curves of alveolar CO_2 tension in each of these types made by Mr. Dodds; he emphasised the striking confirmation of these results, and the enormous variations in alveolar CO_2 tension after a meal seen in certain hypersecretory types.

Dr. R. L. MACKENZIE WALLIS said that his experience had so far been confined to the one-hour test-meal, using the well-known Ewald meal for this purpose. This test-meal enabled one to make a complete analysis of the meal, including the estimation of total acidity, free hydrochloric acid, physiologically active hydrochloric acid, inorganic chlorides, total chlorides, organic acids, nitrogen content, and ferment activity. In carcinoma of the stomach free hydrochloric acid was usually absent, and the active hydrochloric acid much diminished. In addition, there was one very characteristic feature—the relative increase of mineral chlorides. This increase of mineral chlorides in carcinoma of the stomach was due, in his opinion, to interaction of the hydrochloric acid secreted with organic acids derived from the growth. In a series of nearly 2000 cases where this complete test-meal analysis had been carried out several interesting points had been revealed. The test-meal diagnosis had been found to be correct in 70 per cent. of cases of early carcinoma of the stomach—i.e., operable cases. If one included the cases where clinically there was no doubt as to the diagnosis, which had been confirmed by operation or autopsy, the percentage would be considerably raised. In all the cases the tests for occult blood in the stools had been made and proved to be positive on three successive days in all the 70 per cent. correct cases. A number of cases with malignant disease where the stomach was *not* involved had shown normal values or even hyperchlorhydria in test-meal analyses. There was, however, one type of test-meal where the mineral chlorides were raised to the same extent as in carcinoma of the stomach; this occurred when for any reason there was regurgitation of intestinal contents into the stomach. There was thus a definite neutralisation of some of the hydrochloric acid with the production of sodium chloride. This neutralisation affected the physiologically active hydrochloric acid, with the result that this was diminished, and the inorganic chlorides and total chlorides increased. In carcinoma of the stomach there was no such neutralisation since there was very little hydrochloric acid secreted, and further ferments were markedly diminished, or entirely absent, whereas in regurgitation test-meals they were unaffected. The necessary stimulus to produce regurgitation was provided in every case by an excessive secretion of hydrochloric acid. These regurgitation test-meals had been found in chronic gastric ulcer, duodenal ulcer, gall-stones, and appendicular gastralgia, and also after gastro-enterostomy. It was a natural mechanism to produce neutralisation of the excess of hydrochloric acid in the stomach. The fractional test-meal method failed to detect regurgitation test-meals. Regurgitation of bile at the end of a meal was normal occurrence, but the appearance of bile was necessary since by direct observation a clear watery alkaline fluid had been seen to regurgitate into the stomach. This type of regurgitation occurring before the end of one hour after the meal had been consumed was, in his opinion, definitely pathological. The fractional test-meal in its present form was limited in value in that the material obtained was insufficient for a complete analysis of each fraction, and the estimation of the mineral chlorides was as important as the estimation of total acidity and free hydrochloric acid. The combination of the one-hour test-meal with frequent examination of the stools for blood provided a considerable amount of information in the early diagnosis of carcinoma of the stomach—which was likely to remain the most important function of test-meal analyses.

Dr. GEORGE GRAHAM said that he thought a good case had been made out for the use of the continuous test-meal, but the chemical methods employed were not the best available. It was clearly impossible to make a complete chemical analysis every 15 minutes, but it should be possible to do so once in the course of the experiment, preferably at the end of one hour. He understood from Mr. Ryffel that it would be possible to draw off 15–20 c.cm., which should give enough filtered fluid to do a complete analysis of the chlorides by the Prout-Winter method. Mr. Ryffel had not represented his work on the increase of the mineral chlorides in carcinoma quite correctly. The mineral chlorides were usually increased, though not necessarily, but were always greater than the active HCl. This method was not infallible, but, as was shown in the original series of cases and in Dr. Wallis's recent series, it was of great value in the diagnosis of malignant disease. In order to avoid errors due to regurgitation of the contents of the duodenum the test-meal should not be given until the patient's bowels had been thoroughly cleared out. He had recently seen three cases in which the whole character of the chemical analysis had been altered after the bowels had been well opened.

Dr. W. H. WILLCOX was of opinion that the ordinary test-meal, in which a pint of weak tea and toast were given and the gastric contents withdrawn in an hour's time, still retained its value as a method of diagnosis. This meal, from the quantity of liquid available, permitted a much more complete and more accurate analysis than was possible with the small quantities of liquid available with the fractional test-meal. Dr. Willcox advocated the determination of the active hydrochloric acid by the modified silver nitrate titration described by him in THE LANCET in June, 1905, since this gave results more accurate chemically than methods depending on the change of colour of aniline dye indicators such as were employed in the analysis of fractional test-meals. In his experience the presence of organic acids in considerable quantity, as was the case in growths of the pyloric portions of the stomach, materially affected the accuracy of the titrations for HCl with the usual colour indicators. The determination of mineral chlorides as advocated by Dr. Graham was an important part of a gastric analysis and could always be carried out on an ordinary test-meal, but with the fractional meal this was not usually possible. Dr. Willcox emphasised the importance of determining the ferment activity of the gastric contents, and called attention to the method which he described in THE LANCET in July, 1908. By this method the rennin activity could be determined quickly and accurately, and the process was one which had been in constant routine use on all the test-meals analysed in the pathological chemistry laboratories at St. Mary's Hospital for the last 12 years. It had given uniformly reliable results and was a very useful practical method. He had pointed out in 1908 that the quantitative determination of the rennin present in the gastric contents probably gave a fairly accurate representation of the pepsin present. In cases of gastric and duodenal ulcer and hyperchlorhydria a high figure was given for the rennin activity, while in gastric carcinoma and hypochlorhydria the rennin activity was low, and in achylia gastrica the rennin ferment was absent. Dr. Willcox considered that the fractional test-meal gave valuable evidence, and the type of curve given by the free HCl present formed a useful help to diagnosis in such conditions as gastric and duodenal ulcer, gastric carcinoma, and achylia gastrica. Also the fractional test-meal enabled a valuable determination to be made of the time of emptying of the stomach, which was not given by the ordinary test-meal. He was of opinion that the fractional test-meal should supplement and not replace the ordinary test-meal. The combination of the two methods gave very important chemical information as regards the gastric function.

LIVERPOOL MEDICAL INSTITUTION.

AT the last meeting of the Pathological Section of this society, Dr. J. E. GEMMELL, the President, in the chair, the discussion was resumed of Professor J. G. ADAMI'S paper on

The Pathology of Influenza.[1]

Dr. R. J. M. BUCHANAN, who opened the discussion, said he could only speak on the subject from the clinical side. In the epidemic of 1918 about 450 cases of the disease from among the U.S.A. troops were admitted to three of our auxiliary hospitals, to which he was appointed consulting physician. The outbreak was serious. It soon became evident that the cases could be divided clinically into four groups: (1) the mild catarrhal type; (2) the pneumonic type; (3) cases with physical signs of bronchiolitis; (4) cases of profound toxæmia with little or no respiratory phenomena in whom coma-vigil was the rule, and who with few exceptions died. Among the complications profuse epistaxis was not uncommon. Empyema was not common, but occurred in prolonged cases. One double empyema, one pneumothorax, and cases of pleurisy, suppurative pericarditis, and peritonitis occurred. A few developed otitis media and some mastoid abscess. Subcutaneous abscesses were not uncommon. When arthritis occurred it was generally in the knee. One patient had pelvic abscess which burst through the bowel shortly before death. Symptoms of meningitis were present in a few cases, and he understood that in such the pneumococcus is present in the cerebro-spinal fluid. He saw one case of fatal pneumococcal spinal meningitis in which the body was absolutely rigid as in rigor mortis, with marked delirium and no pulmonary infection. The blood in life contained the organism. His clinical observations of the recent epidemic led him to the conclusion that we had to deal with a triple or multiple infection process. Dr. Buchanan then briefly described the history of the previous epidemics, and showed that the same division into groups was seen, even in the 1889–92 epidemics. He thought this similarity in classification in different epidemics supported the theory of multiple infection, and in support of this he quoted Washbourn, Lister, Gochez, Gillespie, Cole, and Sutton and Sevier.

Professor ERNEST GLYNN referred to 7 children in one family who contracted influenza early in September, 1918. Four died, 3 with very marked tracheitis; pneumococci and bacilli of the influenza group were demonstrated. He quoted some experiences of the influenza epidemic among the American soldiers in Liverpool; direct films from the sputa of 13 cases showed pneumococci and influenza group in 5, influenza group in 2; blood cultures from 70 cases showed pneumococci in 9, pneumococci and streptococci in 2, influenza group in 2; 22 post-influenza empyemas showed pneumococci in 9, streptococci in 8, pneumococci and streptococci in 1, pneumococci and *Staphylococcus aureus* in 2, streptococci group in 1, while one was sterile. He quoted several cases in which the bacilli of the influenza group were numerous in the trachea and bronchi, but pneumococci scanty, whereas in the pneumonic lung alveoli the reverse obtained. A mixed influenzal pneumococcal and streptococcal vaccine which he had made was extensively used for treatment of the American troops, but he had no reliable data as to its value. As "influenzal pneumonia" was often accompanied by septicæmia, vaccines seemed inadvisable on theoretical grounds.

Dr. E. CRONIN LOWE, by means of a series of lantern slides and sections, pointed out the well-recognised importance of the post-nasal space and accessory sinuses as the focus of primary infection in influenza. He showed that in the simple pyrexial cases the intensely influenzal mucosa of those areas gave rise to frequent epistaxis, &c., and was associated with a toxæmia. In other cases which developed later the severe fulminating type of influenza, the condition was due to a generalised bacteriæmia, originating in the infection of the congested pharyngeal veins and extravasated blood in the submucosa of this region and carried probably often in the form of minute infective emboli. These, travelling by the normal anatomical route, would be arrested in the terminal arterioles of the pulmonary artery, which are situated around the terminal bronchioles. In this way he considered, as Dr. Herbert French had suggested elsewhere, the rapid and earliest lung infection took place, giving rise to a peri-bronchiolitis of hæmic origin, which would account for the pathological appearances so constantly found present in these more rapidly fatal cases. The protective functions of the ciliated lining epithelium having been thus damaged, a later infection by direct extension from the upper air-passages along the bronchial tract might ensue. He pointed out that from this point of view the three important factors in treatment lay in the promotion of hygiene of the post-nasal space, prophylactic vaccination against the three organisms principally concerned—namely, *B. influenzæ*, streptococci, and pneumococci—while in the actual treatment of the septicæmic type of case the prompt, early, and adequate administration of curative streptococci or pneumococcal sera should from the biological point of view be the right treatment; generally 50 to 100 c.cm. of serum given intravenously and twice daily would be required.

Dr. A. GORDON GULLAN said that when on service with the B.E.F. in the spring of 1916 he observed an outbreak of influenza of a mild type without any respiratory complications, which was chiefly classified as P.U.O. or trench fever. Early in 1917 he noted cases of influenza complicated with pneumonia and other respiratory affections, but in 1918, when he was officer in charge of the Military Hospital, Gibraltar, two severe outbreaks of influenza occurred; the first, in June, was in several cases accompanied by respiratory complications, but in no instance ending fatally; the second, in October, was much more virulent and patients showed signs of marked toxæmia. In this latter epidemic the respiratory type was much more prevalent, especially in the form of lobar pneumonia, often accompanied by general bronchitis and most severe cyanosis; in 355 cases 77 developed pulmonary complications, and of these 16 terminated fatally. It was noticeable that no soldier affected in June contracted the disease in October. In the sputa which were examined the bacillus of influenza and the pneumococcus were found. Dr. Gullan concluded by saying that Professor Adami's admirable review would stimulate clinicians to further pathological investigation.

Professor J. M. BEATTIE also spoke, and Professor ADAMI replied.

LIVERPOOL MEDICAL INSTITUTION AND MANCHESTER MEDICAL SOCIETY.

A JOINT meeting of these societies was held on March 3rd to which Professor E. S. REYNOLDS, Sir WILLIAM THORBURN, Sir WILLIAM MILLIGAN, and Dr. A. E. BARCLAY made interesting communications. These will be published in our next issue.

MIDDLESEX HOSPITAL MEDICAL SOCIETY.—The annual conversazione will be held at the hospital on Monday, March 21st, at 8.30 P.M., when Dr. Charles Singer will deliver an address entitled "Medicine in Ancient Greece."

---

[1] THE LANCET, Jan. 1st, p. 27.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this association was held on March 8th at the Elizabeth Garrett Anderson Hospital, with Mrs. FLEMMING, M.D., in the chair, when Dr. M. ESTHER HARDING read a paper on

The Circulation During and After Acute Infection.

Dr. Harding pointed out that the duty of the circulation is to serve metabolism in all parts of the body. The problem of the effects of acute infection on the circulation therefore involves a discussion of the condition not only of the heart and myocardium, but also of the blood-vessels, the nervous mechanism, central or peripheral, controlling the blood-vessels, and of the blood. She maintained that all these four great divisions of the circulatory mechanism are affected, primarily or secondarily, in acute infections. Her data were gathered chiefly from a study of diphtheria and influenza, but probably similar effects could be demonstrated in many other diseases—e.g., acute rheumatism, typhoid, pneumonia, cholera, &c.

Diphtheria was particularly suitable for studying circulatory changes, because in this disease they are well marked and the complication of pyrexia is practically absent. In severe cases there is a gradual fall of blood pressure, which in the worst cases proceeds up to death. Brodie reproduced this condition experimentally and showed that the fall of systolic pressure was not due to heart failure and that the vaso-motor mechanism was also intact. By a study of the alteration in diastolic as well as in systolic pressure Dr. Harding had been able to show that during the early toxæmic stage of diphtheria, while the systolic pressure falls steadily the diastolic pressure is much more stationary —i.e., the output per heart beat is reduced, but the peripheral vessels maintain their tone. The ratio between systolic, diastolic, and pulse pressure varying from the normal 3 : 2 : 1 to a ratio even of 6 : 5 : 1. These clinical observations had been confirmed experimentally.

Observations on the specific gravity of the blood in toxæmic cases further showed that the slight general œdema, so-called "lymph-logging," was accompanied by definite increase in the specific gravity of the blood due to the actual loss of part of the fluid content which leads to a decreased volume of the blood in circulation. This fact suggested that the circulatory failure of diphtheria might be, in part at least, due to a condition resembling the oligæmic phenomenon described by Zandell Henderson in cases of shock. Dr. Harding described recent experimental work which confirmed this observation.

The indication for *treatment* seemed to be to attempt to dilute the blood and increase the volume in circulation. Saline injections, while temporarily improving the condition, had been found of no lasting value. Experiments with injections of gum saline, hypertonic saline, and with fresh citrated blood had been performed, and with the latter injection good results had been obtained.

Effects of Infection on the Heart.

In discussing the effects of infection on the heart Dr. Harding gave details of the study of the size, rate, rhythm, and quality of heart sounds. Recognisable dilatation of the heart was rare in fever hospitals, probably because of the complete rest enjoined on the patient, but very rapid dilatation might occur where over-exertion was allowed at too early a stage of convalescence. Quickening of the heart, related either to myocardial insufficiency or to low peripheral blood pressure, occurred during most fevers. Slowing of the heart was the rule in certain fevers—e.g., typhoid; it also occurred often in severe diphtheria, and was usually of grave significance. Of abnormal rhythms, curtailed diastole frequently accompanied increased rate. Sinus arrhythmia tended to disappear as the heart quickened. Sir James Mackenzie taught that its reappearance might be taken as a sign of the return to normal, but Dr. Harding found an irregularity which she took to be sinus arrhythmia practically always present in cases of diphtheria with slowed heart-rate. However, Sir James Mackenzie, to whom she had submitted tracings of the condition, suggested that the condition was not of true sinus type and might be peculiar to diphtheria. Extra-systoles not in themselves dangerous were yet a sign of myocardial trouble if they occurred with great frequency. Heart-block and auricular fibrillation were sometimes seen and were more serious. Heart sounds tested with differential stethoscope showed in the early stages of infection, progressive diminution of audibility of first, and progressive accentuation of the second. The pitch of the second sound also rose from day to day during infections. Taking the normal musical interval for a man to be a minor third, for a a major third, and for a child a fourth, Dr. Harding found that the interval might alter to a sixth or even a seventh during circulatory impairment.

The late effects of infection might be grouped under two headings: (*a*) Myocardial weakness; (*b*) weakness of peripheral circulation which might, or might not, be vasomotor in origin. The differential diagnosis between the two types was important from the point of view of treatment. In both the patient complained of feeling slack. In both there was some breathlessness, palpitation, fatigue after mental exertion, and irritability; in both there was an excitable heart, shortened diastole, and poor exercise response.

In the myocardial group the patient was at his best in the mornings after a night's rest, and got more and more tired as the day went on. In the peripheral weakness group, the patient was tired in the early part of the day, but improved with exercise. The myocardial group were breathless all the time and the breathlessness was of the anoxæmic type with curtailed expiratory pause. The peripheral type were only breathless after exertion. In the myocardial group the patient nearly always complained of some pain and tenderness in varying amount. Cold seemed to shrivel up patients of this type, whereas a patient with peripheral weakness often benefited when cold is applied to the body surface. In the myocardial group prolonged rest was necessary, bromides and digitalis being very useful. Strychnine, cold baths, and adrenalin by the mouth first thing in the morning were often very helpful in the second type.

It was important in dealing with long-continued debility following acute infection, not to forget the possibility of functional weakness dependent on a psychological cause. When a patient's resistance was lowered as the result of infection his psychological repressions were rendered less complete, so that his repressed complexes were given a chance to make themselves unpleasantly felt. This condition could be recognised in the relation between overwork or infection and a nervous breakdown. Here rest and seclusion, with freedom from worry, would often result in a return to health, but there were many cases where the disability was unnecessarily prolonged and where a little psychological treatment would put the patient on the road to recovery.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held on March 3rd, Dr. F. J. SADLER, the President, in the chair, when Sir D'ARCY POWER read a paper on

The Palliative Treatment of Aneurysms by Wiring.

He showed Colt's apparatus for the rapid and aseptic introduction of wire into aneurysms and pointed out various points of practical importance in its use. He then gave details of the more recent cases of thoracic and abdominal aneurysm in which he had employed this method of treatment, and the subsequent history of the patients whose cases had been recorded in the Proceedings of the Royal Society of Medicine in 1912. One of the cases was illustrated by a very complete series of X ray photographs showing the wires in position and the changes undergone by the aneurysm during a period of two years. He arrived at the general conclusion that in the majority of cases there was evidence of cure, as the patients were alive and at work 10 and more years after the wire had been introduced. He also appended an interesting table of cases compiled by Mr. G. H. Colt, showing the duration of life from the first recorded symptoms to the time of death in 133 men and 8 women suffering from thoracic or abdominal aneurysms.

The PRESIDENT, Professor A. J. HALL, Professor A. M. CONNELL, Dr. A. E. BARNES, and others took part in the discussion which followed.

QUEEN'S HOSPITAL, BIRMINGHAM.—The accounts for 1920 show a deficit of £20,499, and the committee in their report make a strong appeal for increased support. The income amounted to £24,228, being an increase of £831 on that of the previous year. The expenditure was £44,727, being £7843 more than for 1919. The average cost per bed occupied was £191 9*s.* 10*d.*, compared with £153 15*s.* 7*d.* in 1919, and with £84 19*s.* 5*d.* in the last pre-war year. The most urgent needs of the hospital are an additional sum of £10,000 per annum to meet the increased working expenses, a new medical out-patient department, and an up-to-date operating theatre. Owing to the large debt the hospital was compelled to allocate the legacies received to the current account instead of investing them, unless they were earmarked for a specific purpose. The number of in-patients was 3235, an increase of 317 on the number in 1919. There were 20,868 out-patients and casualties compared with 21,354 in 1919. In the X ray department there were 2903 new patients and 2164 treatments. An electro-cardiograph was installed in October, the cost being defrayed by Mr. and Mrs. Lionel Spiers as an additional memorial to their son, Lieutenant Archibald Spiers.

Reviews and Notices of Books.

PSYCHOLOGY AND PSYCHOTHERAPY.

By WILLIAM BROWN, M.A., M.D. Oxon., D.Sc. Lond., Reader in Psychology in the University of London, Clinical Assistant in Neurology, King's College Hospital, &c. With a Foreword by W. ALDREN TURNER, C.B., M.D. London: Edward Arnold. 1921. Pp. 196. 8*s.* 6*d.*

INTO a small volume of some 200 pages Dr. William Brown has packed as much sound psychological and psychotherapeutic doctrine as is to be found in many larger volumes of a more pretentious nature. He has given us less a mere clinical description of the familiar phenomena of the psychoneuroses than an exposition of the underlying psychological mechanisms and of the principles of a successful treatment. Accepting the method of psycho-analysis in the investigation and treatment of the psychoneuroses, the author is unable to subscribe to Freud's views in their entirety, and indicates in a few closely argued sections the lines of divergence he is compelled to take. Further, he shows how vague and incomplete is Freud's theory of the emotions in contrast with those associated with the names of Ribot, Shand, and McDougall. It is gratifying to note that Dr. Brown is fully aware of the insufficiency of a solely psychological explanation of the phenomena of hysteria; its peculiar physiological disorders cannot be ignored in any causal explanation that claims completeness; yet it is precisely these disorders which the psychologist tacitly neglects. Absence of the plantar reflex in a case of hysterical paraplegia is as integral a symptom as amnesia, but while the latter is accounted for by Freudian theory the former remains unexplained. It is only fair to observe that Freud himself is well aware of the lacunæ in his hypothesis, and Dr. Brown has done useful service in directing attention again to this matter, for it is one which is too frequently passed by. In the chapters on psychotherapy the reader will find succinct recapitulations of the methods developed by Dr. Brown, and already published in various medical journals; and in a last section is a brief yet lucid and critical re-examination of the theories of the interaction of mind and brain, to no one of which, however, does the author seem to commit himself.

Amid all sorts and conditions of modern psychological and psychotherapeutic monographs and text-books this unambitious volume of Dr. Brown's takes rank with the best.

MENTAL TESTS.

1. *Standard Method of Testing Juvenile Mentality by the Binet-Simon Scale.* By NORBERT J. MELVILLE, Assistant Director, Mental Hygiene Committee, Public Charities Association of Pennsylvania. London and Philadelphia: J. B. Lippincott Company. 1921. Pp. 162. 12*s.* 6*d.*

2. *The Intelligence of School Children.* By LEWIS M. TERMAN, Professor of Education, Leland Stanford Junior University. London: Harrap and Co. 1921. Pp. 317. 8*s.* 6*d.*

1. THIS book does for the Binet-Simon scale what Professor Terman's book on the "Measurement of Intelligence" did for the Stanford revision of that scale; it provides definitely standardised methods of stating the problems to the subject and of scoring results. In one respect the standardisation is more complete, for it extends also to the order in which the tests are presented. This order, it must be stated, is somewhat complicated, and possibly equally accurate results might be obtained by a simpler procedure. In the first enthusiasm for intelligence tests the limitations of the Binet scale as indicative of a child's mentality were sometimes ignored. Dr. Melville definitely recognises that the scale gives no reliable criterion of a child's innate intelligence; it shows only "how much an individual has profited from some typical forms of experience and training which the majority of children in civilised countries undergo not only in school but also in the home and on the playground." He insists, further, that the Binet findings must be "corroborated by a thorough psychobiological study of the case," laying stress on the fact that emotional attitude and factors of character, will, and even of attention are quite inadequately, if at all, measured by this scale. Complete directions are given for the carrying out of each test and for recording its results. The pictures and other diagrams required are embodied in the volume itself instead of on separate cards—an arrangement not without disadvantages. Of special value to English readers is the incorporation in an appendix of the complete set of Porteous maze tests which, testing as they do the foresight, the capacity to plan, the practical judgment, and concentration of the child, supply a marked lack of the Binet scale.

In regard to one cardinal point the book provokes criticism. There is fairly general agreement that many of the Binet tests are misplaced in the scale, some by as much as two years. Many revisions have been published—Goddard's, Kussmaul's, Bobertag's, the Yerkes-Bridge scale (which discarded age-tests), and the Stanford revision—but the author of this book frankly prefers to return to the original scale, with all its faults. Admitting that it was based by Binet on the examination of the poorer children in the Paris schools, he maintains that it only requires correction tables for race and social status to make it available for general use, with the possibility of comparable results. From a scientific point of view one cannot but feel that it is desirable to adopt as a basis a scale of more universal validity, and not one based on children of one race and of one social grade. With so many psychologists of different countries at work on these problems the compilation of such a scale should be possible in the early future.

2. Professor Terman's new book is an analysis of the examination by means of the Stanford revision of the Binet scale of children in various grades of American schools, with the double purpose of demonstrating the great differences of capacity existing among children in each grade, and of indicating better methods than at present exist for the classification in schools of exceptional children. It is therefore primarily a book for teachers, but is also of considerable interest to school medical officers who are using the Stanford scale in their examinations of backward and defective children. Of more general biological significance is Professor Terman's claim that, while the social and educational environment of a child contributes to his success or failure with the tests, yet the chief factor is the original endowment, a claim to some extent supported by the fact that the intelligence quotient in children removed to a superior environment was not found to increase in value. Another investigation of medical interest showed that over a third of the cases gave a reduced intelligence quotient after the removal of tonsils and adenoids, while the increase of the others averaged only two points. Both results, however, must be received with caution, for the number of cases tested was too small to justify any general conclusion.

THE OPERATIVE STORY OF GOITRE.

By WILLIAM S. HALSTED. *The Johns Hopkins Hospital Reports*, Baltimore. Vol. XIX. Pp. 71.

HOW many surgeons watching or even performing the simple operation with practically no operative mortality that removal of an adenoma of the thyroid has now become realise that scarcely more than a generation ago this operation was of so great a severity that it was almost considered unjustifiable. The whole history of this change has been most ably traced by Professor Halsted, who has lived and worked at the subject through the whole of this period. The modesty which characterises all his writings allows but little evidence in this monograph of the fact that he has contributed more than any living surgeon to the success which is obtained from the modern operations. So much credit is given to other surgeons that it may hardly be realised that the author is an active participator rather than an historian. The story has been most carefully written, and an enormous amount of trouble must have been taken in searching the earlier literature. Professor Halsted gives accounts of the first more or less experimental operations, and the inclusion of long abstracts from the original papers adds greatly to the interest of the survey, besides showing clearly what wonderful progress has been made in this and other branches of surgery. Even up to 1860-70 any operation upon the thyroid was apparently condemned by the majority of surgeons as a dangerous and unjustifiable procedure. From this time onwards progress was rapid, but in the early days great difficulty was experienced owing to the danger of hæmorrhage. Hence a partial thyroidectomy was regarded as an almost fatal procedure, most frequently the whole thyroid was removed. It was not until several years had elapsed that it was gradually realised that removal of the whole gland was certain to be followed by deleterious effects. Step by step the slow increase in knowledge and the gradual improvement in the operative results is traced, long and careful accounts being given of the work of such men as Kocher, Billroth, Mikulicz, and many others. Real progress dates, however, from about 1879, when artery forceps were introduced and surgeons were thereby enabled to obtain an almost certain control of hæmorrhage. It is difficult to realise that the introduction of these instruments ranks almost with the discovery of anæsthesia and antiseptics in surgical importance, for the three grave dangers to operation were shock, collapse, and sepsis. If anæsthetics overcame the shock by relieving pain and antiseptics overcame sepsis, so also did the artery forceps, by giving a sure means of controlling hæmorrhage, prevent fatal collapse.

The monograph terminates with an account of the author's operation—firstly for partial thyroidectomy and secondly for the enucleation of adenomata; the steps of each operation are beautifully illustrated. Professor Halsted's work must be regarded as one of the classics of surgical literature, which it is essential for every surgeon to read if he habitually operates upon the thyroid gland. Like the rest of Professor Halsted's contributions to medical literature, it is so interesting that the attention of the reader is engaged from beginning to end, and although the bibliography is complete and the abstracts are many there is no portion which can be regarded as dry or irrelevant.

FOR THE LIMBLESS.

A Handbook compiled by Captain H. H. C. BAIRD, D.S.O. The Disabled Society, 48, Grosvenor-square, London, W. 6*d*.

THE aims and objects of the Disabled Society are certainly worthy of public support, being, briefly, the collection and dissemination of knowledge useful to the limbless. The pamphlet now issued is described as a skeleton edition only, later to be amplified in the light of the actual experience of the disabled; in addition, illustrated home exercises for the guidance of wearers of artificial arms and legs are promised in the next edition. Such information should prove of value to the limbless, and we hope that those who for one cause or another do not wear an artificial limb will not be forgotten, as for them exercises are of the greatest importance.

We regret to see no medical name on the executive committee of this society, though there are honorary consultants, and the council includes distinguished members of the profession. The next edition of the Handbook might well receive some attention from one of these, because among some most useful tips and hints by legless men there is one at least of doubtful value. The limbless are advised to treat their stumps with sea-water, methylated spirit, alum and water, and no guidance is afforded as to the efficacy of these washes. The treatment of a stump is in ciple the same as that of any other surface osed to continued pressure, such as the back of a patient suffering from enteric fever. Essentially it must be protected from chafing—that is, in the case of a stump, the artificial limb must fit. Good treatment for any areas subjected to unavoidable pressure is gentle rubbing with the soapy hand in order (*a*) to make the part clean and (*b*) to promote circulation. Only after this should the skin be thoroughly dried to discourage bacterial growth, and only with this object should methylated spirit be used exclusively as a volatile drying lotion. The old idea of hardening the skin instead of keeping it soft and pliable gives results as pernicious to the stump as to the back, or to the nipple of a suckling woman. But on the whole the hints will be found useful.

The information as to the help to which limbless service men are entitled from various Government departments is clearly set out. One further point might be worthy of the consideration of the society. There must be many service men who have not lost their limbs, but have retained practically useless ones. If these could be brought into touch with the society they might also receive and impart much valuable information.

PRACTICAL BACTERIOLOGY.

Blood Work and Animal Parasitology, including Bacteriological Keys, Zoological Tables, and Explanatory Clinical Notes. Sixth edition. By E. R. STITT, M.D., LL.D. London: H. K. Lewis and Co., Ltd. 1921. Pp. 633. 20*s*.

THIS is the sixth edition of the best known work of its kind. The author set himself the task of presenting as much useful information as could possibly be given in the space allowed. All who have ever used the book agree that he succeeded, and all who during the war were engaged in bacteriological work in improvised laboratories far away from libraries were, and are, full of its praise. Every page contains facts and descriptions of methods; even the covers are used for tables. The purchase of this volume will be a useful investment to anyone who wishes to save the time so often wasted in looking up an established fact, a description of a parasite, or an account of a method. He will find in Dr. Stitt's book most of the information he requires.

DISEASES OF CHILDREN.

Aids to the Diagnosis and Treatment of Diseases of Children. Fifth edition. By JOHN MCCAW, M.D. R.U.I., L.R.C.P. Edin. London: Baillière, Tindall, and Cox. 1920. Pp. xii. + 404. 6*s*.

LIKE general medicine, the study of disease in children does not lend itself readily to compression into tablet form, for it is not a limited and clearly circumscribed speciality, but general medicine confined to a particular period of life. The author of this volume of the Student's Aid Series has therefore attempted a difficult task, with what degree of success is demonstrated by the fact that a fifth edition has already been called for. Within its modest limits and at a very moderate cost a surprising amount of information is supplied. To some it may appear to be too concentrated to be easily assimilated, but it is clear that the many have found it palatable. The present edition for the most part has been brought well up to date. We note, however, that no mention is made of the "vitamine" theory of the ætiology of rickets, for which, though still contentious, there is much to be said. On the other hand, the merely speculative view that hypertrophic stenosis of the pylorus is due to hyperadrenalism is given considerable prominence. The statements that "during the first month the child should be nursed every two hours during the day and twice during the night," and that "in infants over a month old one night nursing is sufficient" belong, we think, to an earlier period and mar an otherwise valuable description of breast-feeding. In the section on artificial feeding of infants exception may be taken to the eulogistic mention of a particular kind of dried milk to the exclusion of others, especially as it is not stated that it is a dried milk with modifications. Under the diagnosis of intussusception the absence of a reference to rectal examination or to examination under an anæsthetic constitutes, we think, a serious practical omission. But when all is said it remains true that the author has overcome the initial difficulties of his project with marked ability, and there are few flaws in his book. The title is somewhat misleading, for a good deal more is included than diagnosis and treatment.

BLOOD PICTURES.

Second edition. By CECIL PRICE-JONES, M.B. Lond. Bristol: John Wright and Sons, Ltd. 1920. Pp. 66. 6*s*. 6*d*.

THE second edition of this handbook differs scarcely at all from the first, and the author has wisely refrained from any attempt at elaboration. As it stands the book is a useful guide to the general practitioner, setting forth briefly and lucidly the information which he may fairly expect to obtain from an ordinary examination of the blood. Inasmuch as the general practitioner without previous training is scarcely likely to make the blood examinations himself, the short section on technique might have been omitted. In any case we would suggest that all save experts in constant practice would do well to use separate mixing pipettes for the red and white cells; also that a more viscid diluent than normal saline is easier to work with and gives more reliable results.

FIRST AID.

First Aid to the Injured and Sick. An Advanced Ambulance Handbook. Eleventh edition, revised. By F. J. WARWICK, M.B. Cantab., M.R.C.S., and A. C. TUNSTALL, M.D., F.R.C.S., L.R.C.P. Edin. Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent, and Co. 1920. Pp. 246. 2*s*. 6*d*.

THAT this little book has gone through 11 editions in 20 years is sufficient testimony to its popularity, while the fact that its authors are experienced lecturers and examiners to the St. John Ambulance Association ensures its utility as a text-book. The new edition has been thoroughly revised, some of the illustrations have been improved, and a picture of the diaphragm viewed from the under surface has been added.

PSYCHIATRY.

1. *Psychiatrie.* Tome I.: Traité de Pathologie Médicale et de Thérapeutique Appliquée. Publié sous la direction de EMILE SERGENT, L. RIBADEAU-DUMAS, et L. BABONNEIX. Tomes VII. et VIII.: Par RITTI, JUQUELIER, J. DURAND, MIGUARD, SÉRIEUX, CAPGRAS, LOGRE, BRISSOT, et MALLET. Paris: A. Maloine et Fils. 1921. Pp. 425. Fr.25.

2. *Manual of Psychiatry.* Fifth edition. By AARON J. ROSANOFF, M.D. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd. 1920. Pp. 634. 22*s*.

1. THIS volume of a monumental treatise forms the first of two devoted to psychiatry, and is of a high order of merit, and worthy of the eminence of its various contributors. It is remarkable to note the critical attitude adopted with regard both to psycho-analytic theories and procedures. In the matter of hysteria the Freudian methods are held to have enriched and systematised one of the least happy results of the Salpêtrière school, the culture of hysteria. M. Durand, in the chapter on melancholia, advances a novel idea as to its ætiology. The author adopts Bergson's views as to the *élan* of consciousness, and ascribes the symptoms of melancholia to its enfeeblement and arrest. The whole book illustrates the position of a psychology not as yet influenced by the analytic movement, but based nevertheless upon very solid acquisitions.

2. The French "Manuel de Psychiatrie" of J. Rogues de Fursac has grown considerably since it first appeared in English in 1905, and has been adapted to meet the special demands of American students. The present edition has been strengthened by a chapter very successfully epitomising the theory and practice of psycho-analysis and by 48 pages of frequency tables, to be used in the free association test. There is also a useful appendix, containing intelligence tests graduated for the examination of children aged 3 and subsequent ages up to adult life. One of the most remarkable chapters is that on hysteria, for the most part as Dr. Rosanoff has observed it in a U.S. military hospital. He maintains "that hysterical manifestations can be actuated by motives other than sexual," and defines the hysterical personality as characterised by a total lack of pure or æsthetic morality; that it is at best actuated by prudent morality, and in its typical manifestations entirely by imposed morality. He places the hysterical individual in close relation to the criminal with a certain difference. "Most hysterics are characterised by a trait which is foreign to many criminals—indolence." Such a view is at least robust, and qualifies the rather mawkish attitude which prevails at present towards this affection.

THE STORY OF MY LIFE.

BY W. D. SPANTON, F.R.C.S. Edited by ERIC E. YOUNG, M.S. Lond. London: The Connoisseur 1920. Pp. 403.

AUTOBIOGRAPHIES are many and of varying excellence and importance. Some rank among the treasures of literature and the great documents of human life, as, for instance, St. Augustine's Confessions. Some are merely records of prostituted talents and of how easily a plausible adventurer can take in his fellows, as exhibited in Casanova's Memoirs. Many, including the majority of those which have appeared of recent years, are of no value from the point of view of literature or of anything else; and some, like the work before us, are just a simple tale of an ordinary life lived by a man or woman who has striven to do his or her duty in whatever position of life he or she may be. Mr. Spanton has been a well-known practitioner in the Midlands for many years, and has succeeded in his profession, and done eminently useful work in not purely professional fields. He is best known, perhaps, to the medical profession in general by his having invented an instrument something like a corkscrew for the radical cure of hernia, but the operation which he devised is now practically obsolete.

Mr. Spanton gives us an interesting picture of his early days as an assistant both in the provinces and in London. His memory has played him false in one place, where he says on p. 9 that he met Douglas Jerrold, for he tells us that he was born in 1840 and came to London when he was aged 19, while Douglas Jerrold died in 1857. Spanton completed his medical education at the Middlesex Hospital and after spending some time at the Sheffield Infirmary settled in Hanley in 1866, where he remained until retirement in 1911. The book is an account of a professional life and recalls nothing of any particular importance. In one place Mr. Spanton has forgotten the rules of reticence which should be observed by every medical man, for he goes into considerable detail of various events happening to a certain family, which events were only learned by him in the exercise of his professional duties, and we must express surprise that his editor, Dr. Young, allowed the passages in question to appear in print. Also Dr. Young should have cleared up the following statement (p. 13), which is incomprehensible:—

> "Dr. Morgan mentioned in one of his lectures on physiology that he had observed that, contrary to the usual teaching of that day, during the heart's systole it became shortened. On the contrary, it became elongated. And ..... I set to work to watch the heart's action in frogs ..... and my rather rudimentary observations served to confirm his view."

We can congratulate Mr. Spanton on gaining the confidence and affection of his patients, and one proof of this is given by a poem written in gratitude to him when he was resident surgeon at the old North Staffordshire Infirmary. It will be found on pp. 216-218.

Not only Mr. Spanton is praised, but also his three resident pupils, as follows:—

> "Whether in medical or surgical art,
> May these pupils far excel;
> May Israel's Great Physician's eye
> Round these young gentlemen watch,
> And may it yet be said of them,
> Death nearly met his match."

There is a great deal more of the poem, which is an altogether delightful composition and a tribute which any man might be proud to receive.

The last hundred pages of the book are mainly made up of records of holiday voyages with which Mr. Spanton wisely recruited his activities, both mental and bodily, during his years of practice. He now lives in retirement at Hastings, and we wish him many more years of restful existence.

JOURNALS.

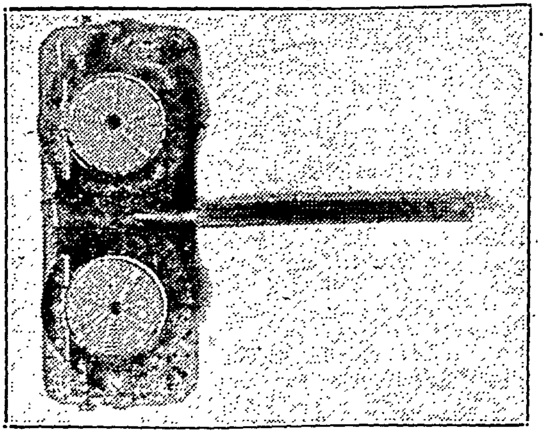
Proceedings of the Royal Society of Medicine, February, 1921. In Dr. Arnold Chaplin's communication to the Section of Epidemiology and Public Health are some interesting statistics of illness and mortality in the Merchant Service, the outcome of his 16 years' experience with shipping companies trading to the East. He found the sick-rate to be 1 in 300. [In the Royal Navy the sick-rate for 1913 was 7 for 300; it is obvious that the statistics are gathered on a different system.] According to Dr. Chaplin, the total mortality stated by the Board of Trade for 1912 was 3·5 per 1000 amongst some 200,000 white seamen, but 5·4 per 1000 amongst the 45,000 lascars; whereas his own experience in the Eastern trade gives 2·6 per 1000 white sailors, and 4·2 per 1000 lascars. The most dangerous disease was pneumonia, the death-rate being 0·3 per 1000 Europeans, 0·8 per 1000 natives. Pulmonary tuberculosis also had a serious mortality, and "all climates appear to favour this complaint in equal degree"; the death-rates are 0·14 per 1000 Europeans, 0·47 per 1000 natives. Dr. Chaplin thinks the spread of the disease is associated with the determination of the native to exclude fresh air from his quarters. He notes that the medical statistics of the Merchant Marine can only be taken as approximate, for it is only ships carrying 100 persons or over which must carry a surgeon, and these form only 600 of the 10,000 ships on the British Register; the statistics of the others depend on the medical knowledge of their captains. To supply these 600 ships with surgeons, about 1000 qualified men are required annually, and their accommodation, Dr. Chaplin says, is, "as a rule, all that can be desired." He proceeds to discuss hospital accommodation, which, in ships carrying third-class passengers, must be provided on the upper passenger deck, and must have 18 square feet for every 50 passengers. No such accommodation is required in other ships, but according to Dr. Chaplin it is nevertheless always provided. The isolation hospital should be aft on a raised deck or over the steering engine-house, and should be built of iron, wood-lined, protected by a double roof, and provided with radiators and plentiful ventilation. The ordinary hospital cabins should be outside cabins, at the end of the alley-way, with the dispensary and surgeon's cabin near by. He hopes a good and safe system may be developed for fumigating ships with hydrocyanic acid; that kills vermin. For ordinary disinfection he uses formalin and permanganate of potassium. In the report of the discussion there are hints of a new Merchant Shipping Bill which will require for each sailor 140 cubic feet of space instead of 120, and 18 square feet of deck instead of 15; hopes were expressed that all questions of the health of seamen should be taken over by the Ministry of Health from the Board of Trade. Several speakers hinted that sailors, so prejudiced against draughts would endure artificially supplied ventilation with warmed air, and General Sir William Macpherson declared that "the prevention of respiratory disease on board ship depended entirely upon the question of ventilation." This has always been urged in THE LANCET. Dr. Major Greenwood drew attention to Sir Gilbert Blane's paper in the Medico-Chirurgical Transactions a hundred years ago, when pneumonia and phthisis were the leading diseases in his statistical returns for the Navy; Blane went on to emphasise the importance of ventilation in ships.

La Médecine.—The first half of the January number of this periodical is devoted to ophthalmology and the second half to oto-rhino-laryngology. Dr. M. Lannois writes on the laryngeal complications of tabes, which are of three kinds—sensory, spasmodic, and paralytic. Of these, the first is unimportant, but the spasmodic affections are of great moment because they occur in the pre-ataxic stage and tend to disappear when the disease has become established; paralyses are more common; energetic treatment with [illegible], and the novoarsenical preparations often does much —Dr. H. Bourgeois discusses tuberculosis of the tonsils; besides miliary tuberculosis and lupus, there are two types, the tuberculous ulcer and latent tuberculosis. The former is rare and is usually secondary to pulmonary phthisis; the latter is found especially in children, the tonsil is normal in appearance, and affection is suspected only from the presence of tuberculous adenitis. The conclusion is that chronic cervical adenitis is not in itself an absolute indication for removal of the tonsils, which should be performed only when they are enlarged or chronically infected.—Dr. L. Dufourmentel is optimistic on the results of treatment of cancer of the œsophagus by radium; he gives a dose of 50 mg. of radium bromide for ten hours, repeated on occasion up to 24 or even 36 hours, and in two-thirds of his cases has obtained immediate diminution of pain with improvement in deglutition and increase of weight, this improvement lasting on an average four or five months; in a third of the cases the improvement was less marked, but very rarely absent. Two patients died of pneumonia respectively, 11 and 9½ months after the application, and two other patients with growths high up in the œsophagus developed, six hours after the application, a kind of paralysis of deglutition with entry of food into the air-passages.—Dr. M. Ramadier has an article on Complete Tonsillectomy interesting to English readers by reason of the light it throws on the totally different practice prevalent in France. Partial removal by morcellement is the operation of choice in those cases where hypertrophy of the tonsils produces mechanical disturbances—that is, chiefly in children—whereas tonsillectomy is preferable in cases where the tonsils are infected, and is usually indicated when the tonsils of adults require operation. The writer prefers local anæsthesia and removal by dissection; the guillotine is not mentioned. There are also articles on the indications for the radical mastoid operation, cancer of the antrum, and several shorter papers. Appended to each is a summary in remarkable English, but too short to be of much value.

New Inventions.

A DOUBLE RETINOSCOPE.

Dr. R. C. Macdonald has brought to our notice a double retinoscope which he has specially designed for refraction work. The shadows are more vivid and the illumination better than with the single instrument, while the operator has the benefit of binocular vision and can correct to an eighth of a dioptre or less any error of his own. Before use the instrument is adjusted to the operator's interpupillary interval for the distance, say one metre, at which he is working. The instrument would be less suitable for fundus examination where the observer's own interpupillary distance is constantly changing. The retinoscope can be used with the usual illuminants; an electric model is also made, and the instrument can be obtained with either concave or plain mirrors according to choice. It is made by Mr. Robert Whitelaw, surgical instrument maker, Woolmanhill, Aberdeen.



THE *Warm Ether Bomb*, described by Dr. S. R. Wilson and Dr. K. B. Pinson in THE LANCET of Feb. 12th (p. 336), is placed when in use in a bowl of boiling water.

THE LANCET.

LONDON: SATURDAY, MARCH 19, 1921.

The Cerebro-spinal Fluid as an Aid to Diagnosis.

THE study of the cerebro-spinal fluid may not as yet have been raised to the dignified level of inclusion in the "ologies" of medicine, but its present-day vogue far exceeds the expectations of the pioneers of twenty years ago. There are few departments of medicine in which diagnosis or treatment is not on occasion materially assisted by resort to the aid furnished by the cerebro-spinal fluid. It has attained the distinction of having books devoted to itself: microscopist and chemist vie with each other in elaborating new tests or discovering new properties to add to the sum of knowledge and, incidentally, to harass the already overburdened student. Serological, immunological, and physico-chemical principles are being applied with zest to the study of the fluid, and no one dare assert that the field has yet been fully reaped, for we do not even know that it has all been sown.

Problems of the origin, formation, and absorption of the cerebro-spinal fluid are not settled, though the general impression derived from experimental observations is that its source is the blood, whence it is separated out by the choroid plexus; its absorption proceeds by diffusion from the subarachnoid spaces and also by lymphatics. Even its function or functions still elude specific determination, apart, perhaps, from its mechanical effect in equalising cerebro-spinal pressure; and as for its precise nature, opinion is still divided on its being a filtrate, transudate, secretion, or dialysate. Fortunately, however, the practical purposes to which its investigation may be put are independent of theoretical uncertainties, though one undecided question is fraught with important therapeutic possibilities—viz., whether the meninges and choroid plexus are permeable. Experiment does not here assist as much as might have been a priori supposed, for the permeability of these structures seems to be very different in disease from what it is in health, and the artificial conditions of experimentation bear but a remote resemblance to what obtains in pathological states. Clinical experience demonstrates the ease with which the fluid can become infected by organisms or impregnated with toxins, since the subarachnoid spaces are continuous with peripheral lymphatics via the spinal and cranial nerves; but the therapeutist is not apparently able to reach the system with equal facility, the choroid plexus, at least in health, offering great resistance to the passage of drugs from the circulation to the fluid. On the other hand, it is well recognised that drugs are absorbed from the fluid into the blood with remarkable rapidity. For this, among other reasons, recourse is had to the more effective, if less natural, method of lumbar puncture. The profession as a whole must by this time be familiar with the diagnostic value of lymphocytosis, positive globulin test, and positive Wassermann test in cases of neurosyphilis, though it is doubtful whether fluid investigation by itself serves to differentiate the clinical varieties of tabes dorsalis, general paralysis, and cerebro-spinal syphilis. Less well known, perhaps, is the syndrome of Froin, consisting of spontaneous coagulation of the fluid, xanthochromia, and a more or less normal cytology, or, in slighter degrees, an increase of the albumin content without xanthochromia; indicative of spinal compression, the syndrome is of the utmost practical importance. In cases of meningitis of whatever kind microscopical examination of the fluid is a diagnostic necessity, and certain changes in glucose content, chlorides, and albumin or globulin are coming to be recognised for their differentiating import. A recent advance has been made by the discovery of the Lange gold-sol test, the essence of which is that colloidal gold in solution is not affected by normal fluid when diluted with a weak solution of sodium chloride, whereas pathological fluid produces characteristic changes for various diseases, recognisable by alteration in the colour of the solutions. The test is peculiarly sensitive and is regarded as of much significance. A "paretic curve," for example, in the coloration of the series of solutions used in the test, has been found with constancy in fluid from cases of general paralysis, which is a spirochætal disease; and the appearance of a more or less similar "curve" in disseminated sclerosis is one of the arguments advanced within the last year or two for an analogous origin for the latter. Still more elaborate investigations by physico-chemical methods to determine specific gravity, viscosity, freezing-point, and H-ion concentration, may serve diagnostic purposes, but have not as yet been shown to be of special practical value.

From the therapeutic standpoint the results obtained in epidemic cerebro-spinal meningitis by treatment via the spinal fluid have been nothing short of brilliant, but in other varieties of meningitis disappointment is too often the outcome. Relief of tension by lumbar puncture has proved efficacious in not a few cases of meningitis serosa circumscripta, in hydrocephalus, and in some forms of cerebral tumour, yet the procedure is merely palliative and of limited applicability in these diseased conditions. Various forms of headache, similarly, are relieved by occasional withdrawal of fluid, and some cases of Méniére's syndrome. Intraspinous treatment of neurosyphilis, in spite of essays innumerable, has given good, bad, and indifferent results alike, and is not yet established on a secure foundation. In fact, there seem to be limitations to spinal fluid therapy as at present practised, and it is conceivable that better results will be obtained if and when the cerebro-spinal fluid system is reached from within rather than from without.

The Bristol Small-pox Outbreak.

THE country as a whole has kept so clear of small-pox lately that it is well to consider the lessons to be learned from any outbreak such as that which has recently taken place at Bristol and fortunately has now subsided. It is quite certain that our security against small-pox and other infectious diseases largely depends upon the constant vigilance of the sanitary authorities, and especially of port sanitary authorities, for it is notorious that a large proportion of the population has not received even the limited protection conferred by vaccination in infancy. It is, of course, quite common for an outbreak to begin with a mild case, modified by vaccination, but in the case of the Bristol dock labourer the attack was so mild than an examination of his face, body, and arms at the time when his wife and baby were down with the disease, revealed no signs of any recent eruption. His arm bore four good scars of infantile vaccination, his age was 29, and his denial of having had any recent indisposition was emphatic. It was only after careful search had failed to discover the source of infection, that an admission by his wife that he had been off work sick for four days after long nightwork early in December led to a second careful examination, and the discovery of the single pustule under the thick skin of the sole of the left foot. It seems fairly certain that had medical advice been called in for this man early in December the nature of his indisposition would not have been suspected. Few practitioners nowadays have much experience in diagnosing small-pox, and these single pustule cases are extremely likely to be missed. Until symptoms give rise to more decided manifestations diagnosis must be very difficult. Fortunately the infectivity of such extremely modified cases is probably slight and limited to the immediate contacts. In the present instance the infection only spread to bed-contacts. The Leicester system, we believe, rather relies upon the fact that with an unvaccinated community the first case is not likely to be missed. Thus the first case runs the chance of a severe attack for the good of the community; the disease is recognised, and the contacts are vaccinated in time to modify or prevent the disease. In the Bristol outbreak the second crop of cases included a severe fatal case in an unvaccinated infant, which led to the disease being recognised.

It is hardly profitable to speculate as to whether, in the public interest, it is better for the first case to be unmodified and diagnosed, or to be modified and liable to escape notice. Medical skill must work towards rendering each person of the community as safe as possible. We have to recognise that a great proportion of the population are combustible material either from being unvaccinated or only vaccinated in infancy, and that, should they contract small-pox, these modified cases are liable to be missed. Vigilance by sanitary authorities in speering back for the original case, and searching out and vaccinating contacts, must therefore be our safeguard. It seems improbable that we shall adopt an efficient system of vaccination and revaccination in this country, at any rate for a long time. Fortunately each individual can protect himself, herself, or their dependents, and no one need have small-pox. The Bristol outbreak ended with the third crop, which consisted of four cases. Of these, one, aged 36, had one good scar of infantile vaccination, and the other three, aged, respectively, 8, 23, and 24, had not been vaccinated at the time of exposure to infection. All four were vaccinated after exposure to infection, one of them (unvaccinated) on the fourth day after exposure, but in the other cases vaccination may not have been secured until five or six days after exposure to infection. The vaccinations all took. Three had a modified and discrete attack, including the girl who was vaccinated on the fourth day. One had a severe semi-confluent attack. All made good overies. Bristol is to be congratulated on its ape.

We must expect many similar outbreaks in the present unprotected state of the community. The Bristol small-pox hospital was in use at the time of the outbreak for early cases of tuberculosis in children, and the children, of course, had to be sent home. Small-pox hospitals are for long periods not needed for small-pox, and possibly more permanent use could be got out of them if, in these days of motor ambulances, groups of sanitary authorities combined to use one of their small-pox hospitals for the reception of the first cases of an outbreak in any of their districts. There would thus be a possibility of dealing with small outbreaks, like that at Bristol, with a minimum waste of hospital accommodation and without having to disturb hospital inmates of a different character.

The Dangerous Drugs Act and the Draft Regulations.

THE announcement of the appointment of two influential committees in connexion with the Draft Regulations under the Dangerous Drugs Act may cause apprehension lest conflicting advice lead to confusion. The conditions of election of the one and the terms of reference of the other should relieve anxiety. The first consists of 10 Members of the House of Commons, who practically form a watching committee pledged to secure the fullest consultation and consideration before the Dangerous Drugs Act Regulations are settled. This committee was the outcome of a large meeting of Members of Parliament recently convened to meet representatives of various interests affected by the Draft Regulations. Before the proceedings commenced the Home Secretary had stated in the House that he was prepared to appoint a small committee "to consider and report, in cases in which the Home Office had not been able to come to terms with the interested parties, what further modifications, if any, can safely be made, having regard to the main principles on which the Regulations are based and which are essential in the public interest for safeguarding the use of the drugs." The names of those forming this Official Committee have now been made public. It includes representatives of the Home Office and four Members of Parliament, one of whom was formerly secretary of the Pharmaceutical Society of Great Britain.

What is needed under the new Act is a schedule to secure public safety, and the Regulations must be drafted with that object, and with no other. But it goes without saying that they should give as little trouble as possible to those who have to work under them, whose professional position must be considered. We hope that the Committee will keep these two big issues steadily before them, trusting medicine and pharmacy to sink differences of opinion for the common good.

RED CROSS SUNDAY.—The Archbishops and the heads of the churches have recommended that the collections on Sunday, Nov. 13th, the Sunday following Armistice Day, should be given to the Red Cross and Order of St. John. The Navy and Army and the Archbishops of Ireland and Wales also join in the appeal. A letter has been sent to the clergy of all denominations announcing this fact and stating that the scheme of the Joint Council of the Order of St. John and the British Red Cross Society covers the case of ex-Service men and cripple children, voluntary hospitals, convalescent homes, and nursing associations, motor transport of sick and injured, infant and child welfare, medical supply depôts, and educational propaganda for the prevention of disease. Donations and subscriptions should be sent to the Joint Council Finance Committee, 19, Berkeley-street, London, W. 1.

Annotations.

"Ne quid nimis."

A QUI MIEUX MIEUX.

THE ancient French proverb, with the suggestion of emulation which it contains, might well be chosen as the watchword of two international bodies at present in the throes of a conflict as to who shall be foremost in well-doing. We refer to the League of Red Cross Societies and the Comité International de la Croix Rouge. It had been hoped that the resolution passed at the meeting of the general council of the League in March, 1920, a meeting attended by representatives of the International Committee, had precluded all possibility of duplicating work. The objects of the League, as defined in this resolution, were as follows:—

I.—To encourage and promote in every country of the world the establishment and the development of the duly authorised voluntary national Red Cross organisation, having as purposes the improvement of health, the prevention of diseases, and the mitigation of suffering throughout the world, and to secure the coöperation of such organisations for these purposes.

II.—To promote the welfare of mankind by furnishing a medium for bringing within the reach of all the peoples the benefits to be derived from present known facts and new contributions to science and medical knowledge and their application.

III.—To furnish a medium for coördinating relief work in case of great national or international calamities.

However, the International Committee now point out that their members attended without any voting rights, and that they never intended to express agreement with the above arrangement. One unfortunate result which has drawn attention to the need for further conference is that recently appeals on behalf of the same object were received by the national Red Cross societies from both international organisations. An article[1] by Sir David Henderson, Director-General of the League, explains the present situation from the League's point of view. The committee have a courteous but weighty rejoinder in their own official organ.[2] There is no doubt either that perfect harmony is possible or that it can only be achieved by a round-table conference. It is equally clear that the Red Cross societies should make themselves vocal at such a conference. Although national Red Cross societies appoint their representatives on the board of governors of the League, neither organisation can be said to have a democratic constitution. At the same time both bodies are democratic in spirit and anxious to consult their constituents, who may well insist that the control of international organisation shall be carried on in peaceful coöperation at Geneva. To the League is deputed the right of organising or building up Red Cross societies. The production of the *International Journal of Public Health* is one of the League's best achievements, and the journal has no competitor. Many of the other activities of both bodies are separate and distinct, and the field of overlap is comparatively small. Nevertheless, the right solution of present difficulties may be an organic union of the two societies. The main objection to this course, mentioned by Sir David Henderson, is that the same international body cannot properly combine the duties of a central agency for the societies both in war and in peace, the war-time function being more properly carried on by such a committee of neutrals as the present International Committee. This difficulty could, however, easily be met by appointing a neutral subcommittee on the occasion and for the duration of the next war, a contingency for which the Red Cross must, however unwillingly, provide.

The meetings of the councils of both bodies in Geneva at the end of this month will give the necessary opportunity for the Red Cross societies to make known their opinions concerning the respective duties of the two central organisations which, as Sir David Henderson says, exist only by their will and for their service. We have every hope that an economy in righteousness will result.

LIGHT AS A REMEDIAL AGENT.

THE Londoner, who, after months of winter gloom, receives the baptism of spring sunshine may be excused for accepting uncritically the therapeutic value of the yellow rays of the solar spectrum. We are brought up to believe that sunshine brings colour to the child's cheek and to deduce therefrom, however rashly, that hæmoglobin, no more than chlorophyll, is properly developed in the dark. Dr. A. Rollier, of Leysin, in bringing the remedial effects of Alpine sunshine before our readers this week, takes some trouble to set out the physical as well as the clinical data upon which his claims are based. Attention has long been directed to the ultra-violet rays of the spectrum in producing cutaneous pigmentation, these rays being absorbed by the melanotic cells of the epidermis and by the lipochrome of subcutaneous tissue and blood plasma, with what fate we do not know, but Dr. Rollier gives reason for not neglecting the less-known bactericidal action of the penetrating infra-red rays, recalling the interesting fact that certain fluorescent substances have the power of transforming short light waves length into long ones, a property which has been claimed for quinine when circulating in the blood. Solar radiations as a whole are not only harmless but seem to be actually beneficial to the cells of the higher animals. Patients undergoing heliotherapy, even when confined to bed, retain good muscular development, which Rollier suggests may be due to direct stimulation of an electrical nature. Varicose ulcers yield to the cicatrising action of the sun, while anæmia and rickets are particularly amenable to sunlight treatment in the Alps. Whole sunshine is thus coming into favour, as distinguished from particular components of sunshine, in somewhat the same way as whole bark and total opium alkaloids are establishing themselves above quinine and morphine. Whole sunshine fortunately, even if thin, is accessible also in the lowland, and the results of conservative treatment of surgical tuberculosis at Alton, as related by Sir Henry Gauvain to the Medical Society of London on March 14th, are not inferior to those of Dr. Rollier at Leysin.

There may not be much to say on the other side and not very gracious to say it, but Dr. R. Crawshaw Holt, tuberculosis officer to the Derbyshire County Council, has had the courage to denounce sunlight as a harmful agent in the human economy at a recent debate before a northern medical society. He might have begun with the classical example of the survivors of the Sicilian expedition, whose eyelids were removed by their inhuman adversaries, and who died miserably from exposure to the full glare of the Mediterranean sun. Dr. Holt regards sunshine as a cause not only of sunstroke, but of anæmia, chorea, and poliomyelitis, and as standing in special relation to such epidemic diseases as typhoid, measles, and scarlatina. He thinks that accident cases admitted to hospital during the dark hours have a better chance of recovery than those admitted during the daytime, and he warns the surgeon against exposing the deep parts to light during operation. Three of his tuberculous patients whose chances of recovery were otherwise good, succumbed to the extra dose of sunlight due to the Summer-Time Act of last year. Incidentally he explains in a delightful manner why children are never so happy as when they are dirty. Dirty hands are not so transparent as clean hands. The dirt protects the delicate subjacent skin sensitive to the malignant rays of the sunlight. It is, of course, in the tropics that sunlight has been most convincingly accused of harmful properties, and it was Dr. L. Sambon who photographed the spectrum of an electric arc after its rays had passed through the skin of an Indian native in order to determine the material to be worn by white-skins to have the same protective effect. Five thousand suits and 5000 hat-linings of orange-red colour were actually issued for American troops in the Philippines on the advice of the Surgeon-General's department. Of late years, however, the actinic theory of sunstroke has been overshadowed by the greater probability of the condition being due to heat exhaustion.

[1] Bulletin of the *League of Red Cross Societies*, December, 1920.

[2] Revue Internationale de la Croix Rouge, Feb. 15th, 1921.

The truth is that little exact work has been done on the effect of light on the human organism. No attempt has been made to separate the various causal factors. Obviously in a health resort many other agents are at work: altitude, surroundings, wind, air temperature, and finally change of scene, that mysterious and potent factor that invalidates all uncontrolled climatic experiments and makes every new method or remedy almost certain of immediate success. It would certainly be well to clarify our ideas of what we mean by the effect of light by excluding both infra-red heating rays and ultra-violet chemical rays. A useful piece of experimental work at Johns Hopkins University is recorded in the first issue of the new American *Journal of Hygiene* (January, 1921). Dr. Janet H. Clark has investigated the action of light as emitted by the iron arc on the rabbit's ear. She cites the observation that exposure of rats to darkness, or to red light, causes an initial decrease in the red count and hæmoglobin index which is evened out in a few weeks by the increasing concentration of the blood. She controverts the prevalent idea that the solar spectrum extends further into the ultra-violet in the tropics, quoting experiments by A. Miethe and E. Lehmann, who found the limit of the spectrum on the violet side precisely the same, whether measured at Assouan, Berlin, or Zermatt. Her own results are to the effect that the far ultra-violet rays agree with the visible rays in producing lymphocytosis, while the near ultra-violet rays have a depressing effect on the lymphocytes and the long waves no apparent effect at all. There is much more work to be done on lines such as these before the application of light as a remedy is placed on a firm scientific basis.

FRACTURE-DISLOCATION OF THE NECK WITH PARALYSIS; RECOVERY.

Dr. L. A. O. Goddu has recently reported[1] the following remarkable case. On Oct. 27th, 1919, a man was hit by a bag of wool in the back of the neck and thrown on the floor. He lost consciousness, and when he revived found his left arm completely paralysed. For a few days there was a great deal of pain in the back of the neck and left shoulder. He remained at home for four weeks and was examined by Dr. Goddu on Nov. 26th. Both arms were extended along the side of the body, with the fingers in a slightly claw-shaped position. He could not move his arms, but could move the terminal phalanges of both hands. The respiration was 45, and attended with some difficulty. Movements of the head, particularly lateral ones, were restricted. There was no grip in either hand. Reflexes were diminished, especially in the left arm. There was moderate atrophy of the muscles of the arms, especially of the left. Sensation on the left side of the neck, left shoulder, and left side of the chest to the level of the second rib was diminished. The X rays showed a forward dislocation of the third cervical vertebra on the fourth. It seemed that to attempt reduction under an anæsthetic, either by open operation or manipulation, would be dangerous. The trouble with the phrenic nerve, which already was interfering with respiration, might be made worse. Therefore, the following method was adopted. Traction with a 6 lb. weight was applied to the head and kept on night and day for three days. Then an attempt was made by pressure in the right direction to reduce some of the pressure symptoms. This manipulation immediately changed the rate of respiration. After 48 hours another manipulation was performed. At this time the patient said that the neck felt better. Next day he was able to use the right arm with a little help. Examination on Dec. 10th showed in the right arm fair strength in the fingers, forearm, and hand, and weak movement of abduction of the arm from the side and of the external rotators of the humerus. On left side grasp, movements of the fingers, wrist, pronation and supination, and extension at the elbow were fair, though weaker than on the right; of flexion at the elbow, abduction, and external rotation there was only a trace. On Jan. 7th, 1920, he could use his arms in all directions, and their strength was greatly improved. Traction was taken off and a Thomas collar applied at the end of the third week; this was worn night and day, and then a permanent collar of leather and steel was worn until the fracture had become firmly united. A second X ray examination on Dec. 15th, 1919, showed that the angulation at the site of the fracture was less and that there was more space between the third and fourth cervical vertebræ, thus relieving the pressure on the cord. At the time of the report—Nov. 23rd, 1920—the patient had practically full use of the arms, though the strength of the left was a little less than that of the right, and there was only slight limitation of rotation and lateral bending of the head.

DISAPPEARANCE OF CONGENITAL SYPHILIS IN THE SECOND GENERATION.

ONE of the many problems of syphilis which is still obscure concerns the possibility of transmission of congenital syphilis to the second generation. Some observers have investigated the histories of children with congenital syphilis with a view to ascertaining whether their parents suffered from acquired or congenital syphilis. Professor Sidler-Huguenin, of Zurich,[1] has attempted to throw light on this problem from another direction. He has examined the progeny of persons born with syphilis, and of 250 such persons he found that 50 had married, and that 36 of these marriages had been followed by the birth of only 65 children. Of the remaining 14 marriages, not one had been fruitful. Incidentally the interesting observation was made that only nine of the 250 subjects of congenital syphilis were known to have attained the age of 60. Only in two cases had as many as four children been born to the subjects of congenital syphilis. With a view to finding out whether congenital syphilis affects the fertility of both sexes equally or not, Professor Sidler-Huguenin classified his material according to sex, and he found that, of 27 marriages, only five were sterile when the wife suffered from congenital syphilis. The remaining 22 marriages had yielded 48 children. On the other hand, as many as nine out of 23 marriages proved sterile when the father suffered from congenital syphilis. The remaining 14 marriages yielded only 17 children. Thus it would seem that congenital syphilis impairs the reproductive capacity of the male considerably more than that of the female. Of 20 mothers with congenital syphilis, 16 gave a positive Wassermann reaction, yet, with only one exception, all their 45 children gave a negative reaction and showed no X-ray signs of syphilis. Of 12 fathers suffering from congenital syphilis, nine gave a positive reaction, yet none of their 15 children gave a positive reaction. Again, none of the 12 women who had married men suffering from congenital syphilis gave a positive Wassermann reaction. Thus it would seem that congenital syphilis is not as a rule, and perhaps never, transmitted from husband to wife or vice versa, or from parent to child. Although the 65 children born to the subjects of congenital syphilis were searchingly examined for evidence of syphilis, it was found only in one case. On the other hand, there appears to be little doubt that the fertility of the subjects of congenital syphilis is much reduced, and that though they do not transmit syphilis itself to their offspring, a few of these are apt to show poor development, rickets, and other signs of inferior quality. Among many other observations of interest was this, that as many as eight women suffered from manifest signs of congenital syphilis at the time of pregnancy, yet none of their 14 children was syphilitic. Professor Sidler-Huguenin recommends a vigorous course of specific treatment before the marriage of a woman whose congenital syphilis is marked by a positive Wassermann reaction.

A MEDICAL TARIFF THEN AND NOW.

WHEN a tariff of medical fees was first promulgated by the Manchester Medico-Ethical Association, not as an authoritative pronouncement but as a guide to medical men, we gave it cordial welcome[1] in terms that showed its issue to be opportune. A further tribute to its usefulness was a letter, published a few weeks later, from the embarrassed secretaries of the Association, admitting inability to cope with the demands for the pamphlet and announcing that in future it would be obtainable only through a bookseller. The brief explanatory preamble to the suggested tariff does not appear to have suffered or indeed needed much alteration in nearly 70 years. Now, as then, the Association pleads the difficulty of attempting to put forward a fair scale of charges for a profession which, "unlike all other trades and professions, continues to claim its remuneration not only according to the abstract worth of its services, but also with regard to the financial status of its clients"; but adds the modest hope that a recommendatory tariff may serve at least as a reference in disputes, and as a useful guide to the young practitioner. The present is the fifth edition; no revision has been made for 28 years, and in view of the enormously increased cost of living the difference between even the original and the present scale can scarcely be described as excessive. The patients are divided into classes according to the rent they pay; the classification of landlords, lodgers, shopkeepers, "notoriously wealthy men of penurious habits," and presumably also of notorious spendthrifts with no reserve fund for illness, is and must be left to the discretion of the practitioner.

1865. SCALE A: GENERAL PRACTITIONERS. *1921.*

—	Class 1.	Class 2.	Class 3.	Class 4.	—	Class 1.	Class 2.	Class 3.	Class 4.
1.	2/6 to 3/6	3/6 to 5/-	5/- to 7/6	7/6 to 10/6	1. Ordinary visit	3/6 to 5/-	5/- to 10/6	7/6 to 21/-	21/-*
2.	A visit and a half.				2. Special visit	A visit and a half.			
3.	Double an ordinary visit.				3. Night visit (8 P.M. to 9 A.M.) ...	Double an ordinary visit.			
4.	2/6 to 3/6	3/6 to 5/-	5/- to 7/6	7/6 to 10/6	4. Detention †	5/- to 7/6	7/6 to 15/-	15/- to 31/6	31/6*
5.	1/6	2/-	2/6	3/-	5. Mileage ‡	2/6 in each class.			
6.	2/6 to 3/6	3/6 to 5/-	5/- to 7/6	7/6 to 10/6	6. Advice at surgery	3/6 to 5/-	5/- to 10/6	7/6 to 21/-	21/-*
7.	2/6 to 3/6	3/6 to 5/-	5/- to 7/6	7/6 to 10/6	7. Advice by letter or telephone	3/6 to 5/-	5/- to 10/6	7/6 to 21/-	21/-*
8.	2/6	2/6 to 3/6	3/6 to 5/-	5/- to 7/6	8. Attendance on domestic servants	3/6 to 5/- in each class.			
9.	21/-	21/- to 63/-	42/- to 105/-	105/-*	9. Midwifery	42/- to 63/-	63/- to 105/-	105/- to 210/-	210/-*
					10. Vaccination at surgery	5/-	5/- to 10/6	7/6 to 21/-	21/-*
					11. Anæsthetics	31/6	42/-	63/-	84/-
					12. Certificates	1/6* in each class.			

* = and upwards.
† = per hour in 1865, over ½ hour in 1921.
‡ = per mile, beyond 2 miles from home in 1865, beyond 1 mile in 1921.

SCALE B: CONSULTANTS.

1865. For the purposes of this Tariff, a Practitioner is considered a Consultant, when his habitual charges are made according to this scale. *1921.*

—	Class 1.	Class 2.	Class 3.	Class 4.	—	Class 1.	Class 2.	Class 3.	Class 4
1.	21/-	21/	21/-	21/-	1. Advice or visit alone or letter of advice	42/-	42/-	42/- to 63/-	42/- to 63/-
2.	21/-	21/- to 42/-	21/- to 42/-	21/- to 42/-	2. Advice or visit with another practitioner	42/-	42/- to 63/-	42/- to 63/-	63/-
3.	10/6 in each class.				3. Mileage beyond two miles from consulting-room	15/- in each class.			

Tariff of fees for general practitioners.—Scale A compares the more important items of the tariffs of 1865 and 1921. Class 1 comprises patients whose house rental does not exceed £26. Class 2: rental between £26 and £50. Class 3: rental between £50 and £100. Class 4: rental over £100.

The tariffs in Scale A are recommended irrespective of the supply of medicine. Surgical operations are not assessed, but the fees allowed by the Poor-law authorities are regarded as minimal. It will be noticed that the tariffs for ordinary visits in Classes 1 and 2 are not even doubled in 1921; also that a much greater latitude is allowed in Class 3, where the majority of non-panel patients will now belong. The inclusion of a tariff of visits to servants reminds us that the panel system is not everywhere regarded with favour, and that people still often require their own doctor to attend their servants. A guinea for a visit to patients in Class 4 may seem excessive in London, where many people are forced by the house shortage to spend much more than the orthodox 10 per cent. of income on rent, but in the provinces this scale would probably work out approximately correct. When all restrictions on rent are removed some allowance may have to be made for a higher rent-to-income proportion throughout the country. Even now the practitioner in his own interests will have to satisfy himself that some fortunate possessors of a long lease are not wrongly classified. The difference in the detention per hour tariff is interesting, the doctor's actual time being assessed higher in 1921; doubtless routine examinations are less extensive and prolonged now that the physician does not depend exclusively on clinical evidence. It is curious that, in spite of improved means of transport, the distance beyond which an extra fee should be chargeable was formerly a radius of two miles, and now is only one mile, from the doctor's place of residence.

Tariff for consultants.—The tariff of fees for consultants in 1865 and 1921 is shown in Scale B.

On the modern tariffs taken by themselves we have little criticism to offer. We rejoice that advice by telephone or letter is assessed at exactly the same figure as oral advice, but are surprised that, in the opinion of the Association, a call at the patient's house should cost him no more than a consultation at a surgery or at the house of the consultant. Pathological investigations, X ray examinations, and so forth are not assessed. The pamphlet concludes with Scale C—special charges in medico-legal cases, life assurance, lunacy, and so forth. We note that the charges suggested for attendance as witness on behalf of any private party vary, according to circumstances, from 3 to 25 guineas, and that a doctor should receive 3 guineas for making or attending a post-mortem examination. It is time that the fee for attendance at a coroner's court as expert for the Crown and for a post-mortem examination ordered by the coroner should be raised from the absurdly inadequate figure of a guinea each, and we recommend a revision of this scale of fees to the consideration of the authorities.

---

RADIUM TREATMENT OF LEUKÆMIA.

IN a recent communication to the Académie de Médecine[1] MM. Rénon and Degrais report that since 1910 they have treated eight cases of leukæmia by applications of radium to the spleen. Although all the patients ultimately died at dates ranging from two months to six and a half years after the commencement of treatment, the immediate effects were remarkably good. Spleens which had filled the whole of the abdominal cavity rapidly diminished from day to day under this treatment, and finally resumed their normal size. The number of leucocytes fell from 320,000 to 70,800, then to 20,000, 7000, and even lower. The myelocytes disappeared and the number of red cells increased. The general condition improved, the fever subsided, the weight increased, and after four to six weeks' treatment a cure seemed to have been effected. Recovery, however, was more apparent than real, for from two to 18 months after cessation of treatment signs of myeloid leukæmia reappeared. Applications of radium were resumed, but with hardly any effect, and death took place in a time ranging from two months to some years after the commencement of treatment. The occurrence of the relapses is attributed by MM. Rénon and Degrais to progressive resistance of the myelocytes on which radium had no longer any effect, whether this was due to habituation of the myelocytes to radium like that of spirochætes to arsenic, or to a fibrous change in the leukæmic spleen under the influence of treatment. The writers think that the best way to retard the appearance of relapses and to diminish their gravity is to apply the radium treatment less frequently, and to make it as intense as possible each time.

PLEURAL REFLEX OR GAS EMBOLISM?

IN the March number of *Medical Science* Mr. W. G. Spencer has contributed a critical review to the subject of air embolism following thoracocentesis. It is curious that though this complication has been known and studied for many decades, it still presents several unsolved problems. Only a few years ago Professor Forlanini was inclined to interpret many, if not most, of the alarming symptoms following puncture of the chest to pleural reflex alone. Professor Brauer, on the other hand, has time and again pointed out that these symptoms can better be explained on the assumption that they are due to gas embolism of the brain and medulla oblongata. A bibliography of the papers dealing with this controversy, and published during the past 20 years, would fill many pages, but to judge by the latest pronouncements most authorities now consider gas embolism to be responsible for practically all the sudden deaths, and not a few of the disturbances from which patients recover after an interval of variable duration. With regard to gas embolism, it appears that it can be caused simply by the escape of inspired air into a ruptured pulmonary blood-vessel. It is, in other words, possible to provoke fatal gas embolism simply by wounding the lung without introducing gas through a hollow needle from without. In *Acta Medica Scandinavica* (1921, Vol. LIII., fasc. vi.) there is a suggestive report of a discussion in which Professor Saugman adumbrated the possibility of a pleural reflex giving rise to signs of hemiplegia. His patient was a woman, whose large pneumothorax had been induced several years earlier. Before a refill, the contour of the collapsed lung was determined by stethoscopic and X ray examination. A pneumothorax needle was inserted at a point far from the lung which could not possibly have been wounded by it. The intrapleural pressure was typical at first, but after some 500 c.cm. of gas had been introduced, the pressure suddenly rose to about 30 cm. of water, although at previous refills it had seldom risen to more than 17 cm. The injection was at once discontinued and the intrapleural pressure lowered, but these measures did not avert signs of hemiplegia on the right side. Paræsthesia developed, but by the third day the patient had recovered. Professor Saugman assumed that pleural reflex had set up focal spasm of the vessels of the brain. This explanation was challenged by Professor Petrén, who pointed out that it is contrary to accepted views that a reflex from an organ should act only on one hemisphere, giving rise to signs of hemiplegia. Professor Saugman's hypothesis as to localised vaso-motor changes in the central nervous system as a result of pleural irritation is interesting, but is it supported by convincing experimental and clinical evidence?

FILARIA LOA AND ITS INSECT HOST.

AN important link in the life-history of *Filaria loa* and its association with certain species of the mangrove fly (Chrysops) were described by Dr. A. Connall at a recent meeting of the Royal Society of Tropical Medicine and Hygiene.[1] That Chrysops was a possible host of *F. loa* had already been suspected by Manson and others, and sufficient proof that this is the case is supplied by the results of Dr. Connall's observations made in Lagos, West Africa, in 1917. The work consisted entirely of dissections of mangrove flies caught at Sapele, near the coast, about two days' journey from Lagos, during the period of eight months between March and October. The laborious work of dissection was carried out by Mrs. Connall, and in all 2255 specimens of *Chrysops silacea* and *dimidiata* were examined, 2006 belonging to the former and 249 to the latter species. Sixteen specimens of *C. silacea*, or 0·8 per cent., and six of *C. dimidiata*, or 2·4 per cent., were found to be infected with *F. loa*. The wettest months of May, June, and July provided the largest number of flies. The positive specimens were nearly always heavily infected, the filariæ being usually present in hundreds, for the most part in the thoracic muscles, and in one insect to the number of 427. In two flies filariæ were found among the mouth parts. The creek district of Sapele, it was pointed out, provided a population a considerable percentage of which is infected with *F. loa*, carrying the adult filariæ in their tissues and showing the presence of embryos in the peripheral blood, and many of the Europeans also contract Calabar swellings. In this area there also exist Chrysops in large numbers, a certain percentage of which have been shown to be infected with filaria. There is therefore justifiable ground in regarding Chrysops as an intermediary host of *F. loa*. No feeding experiments were carried out, and they are likely to be attended by considerable difficulties in the raising of the adult insect from the pupa; the use of an insect free from previous filarial infection has to be insured, and reliable experimental results obtained from feeding the uninfected fly on an infected patient.

THE HANDICAP OF THE LEFT-HANDED.

IN a paper on Sinistrality in Relation to High Blood Pressure and Defects of Speech, Clarence Quinan[2] reviews the literature and brings forward the results of observations made with regard to these points on 142 inmates of the San Francisco Home for the Aged. In addition to the ordinary form there are crossed forms of left-handedness which are latent and do not attract attention unless they are sought for; left-eyedness is not uncommon in the right-handed, and, conversely, right-eyedness is common in sinistrals. The ætiology of the mixed forms is obscure, but in some instances it may be due to a compulsory change of handedness in early life. Approximately 4 per cent. of normal persons are left-handed, and it appears that there is some evidence to show that sinistrality is hereditary and implies a relative inferiority in the organisation of the central nervous system, for stammering occurs from three to seven times more often in sinistrals as compared with dextrals. Among 600 men between the ages of 44 and 89 years there were found to be 42, or 7 per cent.; sinistrals—namely, 14 pure (left-handed and left-eyed), 14 crossed (left-handed and right-eyed), and 14 crossed (left-eyed and right-handed). Comparison of the systolic blood pressure in these sinistrals with that of 100 dextrals showed that a high systolic blood pressure is more frequent in left-handed than in right-handed persons. Thus among 100 pure dextrals with an average age of 69 years 54 per cent. had a systolic blood pressure under 150 mm. Hg, whereas in the groups of sinistrals, all with a lower average age than the dextrals, the percentage of cases with a systolic blood pressure of less than 150 mm. Hg was always under 30. Quinan does not refer to right- or left-leggedness, and as we are ignorant of how much has been written on this subject, Dr. W. K. Sibley's article,[1] now more than 30 years old, may be recalled; he concluded that the majority of people are naturally or artificially right-handed and left-footed, and that as the left leg is stronger than the right there is a tendency to turn to the right in walking, as is shown by the almost universal direction to "Keep to the right"; this right-handedness and left-footedness of most human beings is, in his opinion, an attempt on the part of Nature to preserve as far as possible a bilateral individual, for if the body were wholly right-sided asymmetry would probably result.

THE MORPHOLOGICAL DIAGNOSIS OF PLAGUE.

THE case of bubonic plague described in our columns on March 5th by Dr. V. M. Synge and Dr. J. W. Bigger is of special interest from the public health standpoint, as it occurred in a woman who lived a quarter of a mile from the docks and no source of infection could be discovered. The authors were inclined to incriminate a cat known to be of an adventurous nature. Obviously similar cases may come to the notice of any practitioner in a maritime town, and it may well be borne in mind that the diagnosis of plague can be made in many cases by microscopic examination alone. In no condition other than plague do bacilli with the morphological characters of the plague bacillus occur in large numbers in the lymphatic glands. We reproduce again the micro-photographs of the Dublin case, as these were not printed clearly in some copies of the previous issue.

Plague Bacillus in its Various Forms, as seen in Direct Films and after Culture, in the Case of Plague occurring in Dublin described by Dr. V. M. Synge and Dr. J. W. Bigger.

THE THYMUS GLAND IN GRAVES'S DISEASE.

IN his Harveian lecture delivered on March 17th Dr. Leonard Williams took as his subject the Thymus Gland in Everyday Life, proposing to reinstate as an important member of the endocrine group an organ which had recently fallen into neglect. After sketching the development of the gland and its relation to asthma, he went on to discuss the relationship between the adrenals and the enlarged thymus gland, with special reference to Graves's disease. Dr. Williams said:—

> In this curious and disfiguring malady, disfiguring both physically and mentally, there are two facts so salient that any intelligent understanding of the condition demands not only that they be recognised, but definitely co-related. The one is the enlargement of the thymus; the other is the over-activity of the suprarenals. The former, the enlarged thymus, which occurs in about 85 per cent. of the cases, is an astonishing event, for Graves's disease is to all intents a female disease and the thymus to all intents a male organ. The latter, the over-active adrenal, is a fundamental event, for without it the full clinical picture of the disease would not exist. Now the adrenal contribution to the liquor sanguinis makes for masculinity; it produces energy and increases the combative instinct. Here, then, you have two organs, the thymus and the adrenal, both of which are predominantly male, playing leading parts in a disease which is predominantly female. What is the explanation?
>
> I have been seeking the answer to this question for a very long time, and I now believe it to reside in the histological fact which I have already quoted from Sir Edward Sharpey-Schafer—namely, that "an accessory thyroid is often met with in the substance of the thymus." This, then, would seem to be the train of events. In response to a toxic stimulus, almost invariably of intestinal origin, the external thyroid hypertrophies. In those women who have an accessory thyroid embedded in the thymus this hypertrophies too. This in its turn stimulates the thymus into recrudescence, and there is produced what is practically a new growth situated in the critical space between the manubrium sterni and the vertebral column, which presses upon the various important structures converging into that anatomical Clapham Junction. The part of the adrenals is not so clear. It may be that they are stimulated into increased action by the same toxin which provokes a hypertrophy of the thyroid, or it may be that the pressure of the enlarged thymus upon the cervical sympathetic calls forth an increased adrenal activity, for the association between the sympathetic or autonomous nervous system and the adrenals is so close that they are grouped into one under the name of the chromaffin system. Or, again, it may be that the mere hyperactivity of the thyroid produced by its endeavours to fight the toxin evokes a concomitant hyperactivity of the adrenals, for the thyroid and suprarenals are known to act synergically. Which, if any, of these suggestions be the right one, the fact remains that in Graves's disease the suprarenals are in riotous activity, which explains the exophthalmos when it is bilateral, and the alteration in character from docile to aggressive, which is such an outstanding feature of the disease. When the exophthalmos is unilateral or more pronounced upon one side than another irritation of the sympathetic by the pressure of the thymus is the cause.

The remaining portion of the address was devoted to the thymus in relation to chlorosis and headache, and the treatment of the resulting conditions.

A National Health Week, organised by the Royal Sanitary Institute, will be held during October next.

THE House and Library of the Royal Society of Medicine, 1, Wimpole-street, London, W., will be closed from Thursday, March 24th, until Tuesday, March 29th both days inclusive.

THE LANGHAM TELEPHONE EXCHANGE:

MEDICAL MEN'S NEW NUMBERS.

WE gave last week a list, as complete as possible, of the telephone circuits of medical men and dentists practising in the Harley-street area which were transferred on Saturday, March 5th, from the Mayfair to the Langham Exchange. We anticipated that the list supplied to us was not quite complete and now make the following additions:—

Mayfair.	Subscriber.	Langham.	Mayfair.	Subscriber.	Langham.
5146	Baly, C. Peyton	1686	3407	Goodwin, Aubrey	2098
4262	Biggs, G. N.	1872	4209	Gow, John	1184
1858	Burrell, L. S.	1858	3815	Gray, A. M. H.	1982
3560	Chandler, F. G.	2186	933	MacCormac, Henry	2670
3929	Clayton-Greene, W. H.	1960	2631	Pitts, A. T.	2631
4117	Coffin, Stephen	1910	2084	Rees, J. R.	2338
1349	Fox, R. Hingston	1349	285	Vlasto, M.	1064
6180	Gauvain, Sir H.	1456	88	Wilson, S. A. K.	1018

We shall be glad to publish any further necessary corrections.

THE GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION.

AT an Executive Committee held recently a number of matters of public interest came up for consideration.

Reappointment of members.—Official notification was read of the reappointment of the following members of the Council: Dr. Benjamin Bloomfield Connolly, as representative of the Society of Apothecaries of London for one year from Dec. 10th, 1920; Sir Arthur Chance, F.R.C.S.I., as representative of the Royal College of Surgeons in Ireland for one year from Feb. 6th, 1921; Dr. Sydney Russell Wells, as representative of the University of London for one year from Feb. 24th, 1921.

Restoration of names to the Register.—The Registrar reported that the names of the undermentioned practitioners had been restored to the Medical Register, from which they had been erased on account of failure to communicate their addresses to the Registrar:—

Addinsell, Augustus W.
Dakin-Smith, William H.
Ellis, Robert S.
Ennis, John C.
Fuller, Ashbury J. S.
Fyzee, Ali A. H.
Griffiths, Alfred T.
Hawkins, Charles T.
Hayward, William H.
Herbert, Charles A.
MacLaren, James P.
Milne, John B.
Nash, Charles H.
Oldham, Ralph S.
Somerset, Vere E.
Strong, Clement P.
Turnbull, Arthur
Wright, Reginald H.

Reciprocity with Spain.—A communication was received from the Privy Council enclosing a translation of a Royal Decree relating to the practice of medicine and dentistry in Spain, with a view to applying to Spain the provisions of Part II. of the Medical Act, 1886. The Decree sets out that, henceforth, only doctors and dentists who have obtained their qualifications in countries with which Spain has reciprocal relations will be authorised to practise; and that temporary authorisations now in force will terminate as soon as the period expires for which they were granted. It was resolved to inquire (1) what privileges of practising in Spain would be afforded to registered British medical practitioners in the event of reciprocity being established with that country, and (2) into the course of study and examinations prescribed for the Spanish diploma.

Indian universities and midwifery.—After considering the replies received from Indian universities and colleges to a circular letter regarding the course of study in midwifery pursued by candidates for Indian medical diplomas, it was resolved that such diplomas under existing conditions did not furnish a sufficient guarantee of the possession of the requisite knowledge and skill for the efficient practice of midwifery within the meaning of Section 13 (i.) of the Medical Act, 1886, and that unless the requirements are forthwith brought into accordance with the Council's resolutions recognition of the respective medical diplomas must cease.

The buff telephone book.—The question of the appearance of names in this book was informally under the consideration of the Committee in November. The Bar Council had sent a communication stating that it considered the book to be issued for advertising purposes, and that it had resolved that it is not in accordance with the etiquette of the profession for barristers to insert their names in the book. The Law Society had so far felt a difficulty in expressing an opinion that it was contrary to the etiquette of the profession that solicitors should insert their names in the book. The view the society had always expressed upon the question of directory advertising was that so long as a directory was open to the whole profession without distinction, whether for payment or not, there was no objection to a solicitor allowing his name to appear in it. The Royal College of Veterinary Surgeons desired to be informed of any decision to which the Council might come. It was resolved:—

> That the insertion of the name of a medical practitioner for payment, whether with or without typographical display, in a list issued to the public, and purporting to be a list of local medical practitioners, which is not open to the whole of the profession without such payment, is not in accordance with profesfessional standards in respect of advertising, and might be held to bring a practitioner so advertising himself within the terms of No. 5 of the Council's warning notices.

The Registrar was directed to bring this opinion to the notice of all persons making inquiry respecting their professional position in regard to this question.

Correction of the Medical Register.—The Registrar reported that as the result of the issue of voting papers for the elections of direct representatives for the three divisions of the United Kingdom in November, 1919, 2277 papers in all were returned through the dead letter office. Although there was no legal obligation to do more than send an inquiry under Section 14, very great pains were always taken to prevent the unnecessary removal of names. By the courtesy of the editors a list of those who could not be traced was published in *The Lancet* and *British Medical Journal*. As a result only 484 names had to be erased; in other words, 1793 practitioners were saved from the consequences of their own neglect to keep a correct address in the Register. In consequence of the close relationships which have been established between the Ministries of Health and Pensions, the Boards of Education and Trade, Insurance Committees, chemists, &c., and the Council, it was far more difficult now than it used to be for persons whose names did not appear upon the Register to continue to practise as if registered. The system which was in force before the war for correcting the Register had now been followed again, and circulars of inquiry had been sent to all practitioners from the letter "P" to the end of the Register who did not communicate with the office in the course of the year 1920. These would be followed up and the necessary corrections or removals made.

VITAL STATISTICS OF 1919.

REGISTRAR-GENERAL'S ANNUAL REPORT.

THE birth- and death-rate conditions in 1919 were in some respects exceptional. During the first half of the year the birth-rate fell to the lowest point on record, although in the latter half of the year it recovered considerably. The birth-rate for the entire year stands at 18·5 per 1000, which is 5·3 below the rate for 1914—the last year unaffected by war conditions. The death-rate in 1919 was 13·7, being the lowest on record with the exception of the rates for 1910 and 1912, notwithstanding the heavy influenza fatality in the spring. Among common infectious diseases, the death-rates from enteric fever, measles, and whooping-cough were the lowest on record. From tuberculosis, likewise, the mortality was the lowest hitherto observed, in spite of the influenza epidemic. From cancer the death-rate in 1919 was the highest yet recorded. This disease presents the one great exception to the general tendency to decline of mortality.

In 1919 the excess of births over deaths was 188,235, as compared with 362,354 in 1914—the last year influenced by peace conditions. The very low excess in 1918, which took no account of war casualties, except 3827 deaths at home from wounds, was due to the great mortality from influenza, in conjunction with the unprecedentedly low birth-rate. In 1919 both factors were still operative in keeping down the natural increase, although births had slightly increased, and influenza mortality was much less formidable than in the previous year. It is important to note that there was not in 1919, as there had been in the preceding year, a large mortality from warfare abroad. The statistics of 1919 support the general belief that the best criterion of the health of a people consists in the mortality in the earlier days and weeks of life. It is probably for this reason that Dr. T. H. C. Stevenson, in his present review, returns to an examination of this question. He not only obtains additional support for the general belief, but supplies a series of instructive tables which will be appreciated by medical officers of health, and which throw new light on the whole question of mortality and its causes in early life.

Saving of Life in Infancy and Childhood.

Of the deaths registered in 1919, only 12·2 per cent. were those of infants under the age of 1 year. The proportion has fallen rapidly in recent years because of the reduction both in infant mortality and in the birth-rate. So recently as 1901–10 the percentage was no less than 22·6. Infant mortality, in terms of total births, was equal to 89 per 1000, and was 15·2 per cent. below the average in the ten years immediately preceding. It is the lowest rate hitherto reported.

The results of life-saving efforts vary considerably in different stages of the first year. The outstanding feature of the year's record is that the mortality of the first four weeks of life was higher in 1919 than in any year since 1911, while at the succeeding ages it was unprecedentedly low, notwithstanding the prevalence of influenza. The deaths above the age of 1 month have long been recognised as the most preventable, and success in reduction of infant mortality has mainly depended on this circumstance. But until the setback in 1919 the recorded rates afforded grounds for hope that the first weeks of life were also beginning to participate in the improvement, as the result of administrative effort in recent years. The decline in mortality at ages above four weeks is noteworthy, but in this case the most remarkable feature in the year's record is the unusually low mortality from infectious disease. The importance of this cause of mortality increases with age, and if infectious disease be omitted from comparison the advantage of 1919 over previous years practically disappears. The only infectious diseases specially important at this age in 1919 were measles and whooping-cough, the loss of life from both of which was exceptionally low. As already stated, infant mortality varies enormously in different parts of the country, the rate ranging from 108 per 1000 births in the larger towns of the north of England to 64 in the rural districts of the south. From the very first day after birth the excess of mortality in the north is well marked. After the first day the regular increase from south to north becomes the rule. In each of three years cited for comparison much the highest rate for the first day of life has been returned from the rural districts of the north, so that it seems as though the birth risk is for some reason at its maximum there. In Wales there was a similar rural excess, but not in any part of England. Therefore, if defective midwifery service in remote districts be the cause, this does not apply to the midlands or the south.

The increased mortality of the first four weeks after birth is now shown to be limited to the first two, the third and fourth having remained almost stationary. The increase in the first two weeks is very general, applying with few exceptions to all types of area throughout the country.

Causes of Infant Mortality.

From an analysis of the causes of infant mortality we learn that in each period after the first four weeks the mortality from the principal causes, except influenza and the respiratory affections, was lower in 1919 than in the years immediately preceding the war. It was lower than in 1918 from all the specified causes. In the case of whooping-cough and the other common infectious diseases the reduction was very great; specially noteworthy were the further large decreases from tubercle and convulsions, beyond the low records for these causes in 1918. The mortality ascribed to tubercle was less than one-third, and that to convulsions was less than half of that so returned 14 years previously. It may be said of these causes, and this is equally true of diarrhœa, that they are gradually disappearing from our returns.

The London mortality from convulsions was, as usual, much below, and that from Wales was above, that of the country generally. London has for years led the way in the elimination of this unsatisfactory form of return. Among other causes deserving mention the following may be selected. Diarrhœa and enteritis with the lowest infant mortality except that of 1912; syphilis, which has declined since the startling rate for 1917, although the pre-war level has not yet been regained; overlying, which has presented a remarkable fall since 1914, so that the 1919 rates were less than half those of a few pre-war years; and atrophy and debility, which shows the lowest mortality ever returned for England and Wales. The unusually high mortality in London from these causes, noted in last year's report, has now disappeared, the rates being again as usual, much below the average. We find that each of the principal causes contributes to the excessive mortality of the north of England and to the favourable position of the south, and this is true for each class of area in both cases. In proportion to the mortality thus returned, convulsions is the chief contributor to the difference, for while its share in the total mortality is less than 7 per cent. it accounts for 22 per cent. of the difference between north and south. Atrophy, with a share of 16 per cent. in mortality, accounts for 26 per cent. of the difference, and prematurity, to which half of the total mortality is due, accounts for 41 per cent.

The great excess of mortality in the rural districts of the north, and the fact that it exceeds that of the northern towns, great or small, are features common to the statistics of recent years. This large excess is mainly attributable to the indefinite headings atrophy and convulsions. There is no appreciable excess from premature birth. In the case of rural Wales, however, the heavy excess of mortality from convulsions must largely represent deaths which elsewhere would be attributed to other causes, and so possibly to prematurity.

Mortality in the First Five Years of Life.

Notwithstanding the continuance during the spring of the influenza epidemic, which had quite exceptionally raised the mortality of 1918 at these ages, the rate in 1919 was very low. With the possible exception of 1916, there has been no year recording so low a figure, and if influenzal fatality be deducted the rate of 1919 is reduced much below that of any previous year.

It is curious to observe that mortality at age 0-1, measured in terms of estimated population at that age, shows no decrease from the corresponding rate of the preceding year, notwithstanding the decline in infant mortality. The anomaly is explained by the history of the birth-rate during the year. The exceptionally scanty births of the first two quarters alone contributed to the mid-year population on which the rate is founded, whereas the numerous births of the last quarter are taken into account in fixing the infant mortality-rate. The population basis exaggerates the mortality of 1919, and that in proportion to births diminishes it; in the one case because more deaths of very young infants accompanied the relatively high birth-rate of the last quarter than the mid-year population would account for, and in the other because the births of the last quarter, which naturally yield a lower mortality within the year than those of earlier quarters, were in exceptionally high proportion. Mortality in the second year of life was lower in 1919 than in any other of the last few years, and therefore almost certainly the lowest yet experienced, but at each of the three succeeding years, 2–3, 3–4, and 4–5 lower rates were recorded in other years. The tabulation of deaths of infants by separate months of age has been continued throughout the second year of life. The process has not been continued beyond the second year because of difficulties connected with the estimates. The data for the first two years have been obtained by deduction of deaths from births, without any allowance for migration.

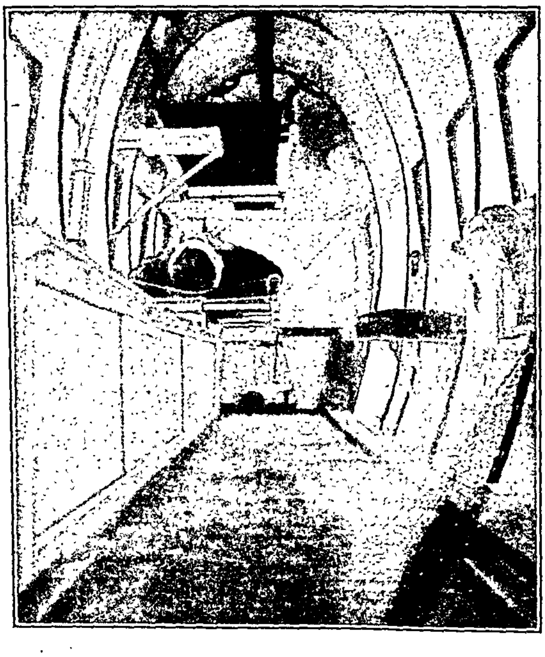
Migration becomes increasingly important with increase of age; and in view of the approach of the Census it has been thought best to limit the estimates to the first two years of life.

Dr. Eustace Greaves has been appointed an Official Member of the Legislative Council of the Island of Saint Vincent.

AEROPLANE AMBULANCES.

THE idea of removing wounded men from the field of battle by means of air service is no new one. It originated in 1910 from Dr. de Mooy, of the Dutch Medical Service, was further ventilated before the war by Mr. Ch. Julliot, of the French Service de Santé, and under pressure from Dr. A. Chassaing, who was both médicin-major and Parliamentary deputy, was nearly realised on the French front in 1918. After an interval of three years French Ministers of State are now reported to be considering the provision of numbers of large medical aeroplanes for use in colonies where other transport is difficult. A machine recently officially inspected at the Villacoublay aerodrome is a Bréguet biplane to carry two stretcher or four sitting cases in charge of a nurse and is provided with steriliser and operating-table.

The aviation department of Messrs. Vickers, Ltd., have sent us details of a machine of the Vickers Vimy commercial type, modified to fulfil the duties of an aeroplane ambulance, and constructed in accordance with the requirements of the Air Ministry; it is capable of carrying at a height of 6500 feet, and at a speed of 109 miles per hour for five hours, the following load: 1 pilot, 1 mechanic, 1 doctor, 1 nurse, 4 stretcher or 8 sitting cases, and 100 lb. weight of medical stores. Fitted with two Napier Lion 450 horse-power engines, and carrying a wireless installation, the machine can climb with full load to the above height in 10 minutes; it can also fly with one engine out of action. The shell is watertight and specially constructed in case a descent on the sea is necessary; an opening is provided in the front of the luggage compartment (under the pilot's seat) whereby stretchers may be loaded and unloaded without any turning of corners. Sitting and walking cases can be admitted through the ordinary doors in the side, which are constructed of a size adequate for rapid evacuation in case of emergency. In the photograph of the interior here given the stretcher racks (which can be folded out of the way of seated cases) are shown in position to hold stretchers. Clearance and lateral floor spaces are allowed for sufficient to facilitate in every way the handling of stretcher cases; ventilation is provided by a fan fitted in the front wall of the cabin; this fan drives air through a screen, which is kept moist, and can be operated when the aeroplane is stationary on the ground. Regulation of the flow of water down the screen will admit the maintenance of an even and cool temperature in tropical countries. A lavatory pan is provided, supplied with a 15 gallon water-tank, and flushed into a receptacle which is easily detached for emptying and disinfecting; a wash-basin is included, and there are separate smaller tanks for washing, drinking, and cooling water.



Interior of the Vickers Vimy ambulance aeroplane, showing a stretcher case in position for transport.

The uses of such ambulance aeroplanes will be considerable in areas where roads do not exist, or where they are too crowded to admit of rapid transport of urgent cases. For small tropical or mountain expeditions a supply of such aeroplanes might be very helpful.

MEDICINE AND THE LAW.

Riders at Coroners' Inquests.

AT a recent inquest held before the deputy coroner at Brixton, the subject of inquiry was the cause of death of an infant. As to this there was medical evidence founded upon post-mortem examination, and a verdict was found in accordance with it. Evidence was, however, also given that a medical man who was not present as a witness, Mr. E. Nundy, had been sent a message asking him to call at the house where the mother lived. This he had done on the following day, as he was attending to the practice of a colleague on whose panel the woman alleged herself to be. When Mr. Nundy came he found that he was being asked to certify as to the cause of death of a child which had died some hours before the summons to attend had reached him, and he quite properly refused to give any certificate, satisfied himself that the child was dead, and recommended that the mother should be removed from her unsuitable surroundings to the infirmary. She refused to go to the infirmary, but Mr. Nundy, nevertheless, as he informs us, took considerable trouble in arranging for her removal thither. The woman, however, complained at the inquest on account of his not having treated her, with the result that the jury added a rider to their verdict asking that Mr. Nundy should be censured for not having given her proper attention. Clearly this was a most improper finding upon a subject quite outside the scope of the inquiry. Apart from the obvious injustice of censuring a man who had been given no opportunity to give his own version of the occurrence in question, the inquest was held in order to ascertain the cause of the death of the child. The mother's health and her grievances, real or imaginary, against an absent doctor were not the concern of the jury or the coroner.

It is a curious coincidence that Mr. Nundy should have found himself the subject of a rider to a verdict at an inquest, arrived at in his absence, in a case in which he had no evidence to offer as to the death the subject of inquiry. In a pamphlet before us, entitled "Coroners' Courts: Their Uses and Abuses,"[1] he has made his principal topic for criticism and protest the licence accorded to coroners' juries to find "riders." It is to be noted that Mr. Henslowe Wellington in his work on coroners[2] can find no authority justifying the addition of the "rider," as an expression of opinion accompanying a verdict which latter is a finding of fact. Nor do they appear to have any history, but have probably grown up and increased in frequency more or less unnoticed. They do not seem either to have any great effect in promoting legislation or otherwise. Perhaps, when the long-postponed reform of the law relating to coroners takes place, this detail of the procedure in their courts may receive consideration. There seems to be no parallel in other courts for the rider, except perhaps the recommendation of a prisoner to mercy at a criminal trial. That, however, deals with a topic of limited scope, and relevant to the matter in hand. The rider at inquests frequently is neither, and if not used with more restraint may work grave injustice.

---

Everett v. Griffiths and Anklesaria.

The House of Lords recently dismissed the appeal of the plaintiff Everett in this action. It will be remembered that he sued the first-named defendant, the chairman of the board of guardians of St. Mary, Islington, and Mr. K. A. Anklesaria, the medical officer of the workhouse, for damages in respect of his alleged false and unlawful certification as a person of unsound mind. At the original trial the Lord Chief Justice, upon the jury failing to agree, entered judgment for the respondents on the law. The Court of Appeal, by a majority consisting of Lords Justices Bankes and Scrutton, Lord Justice Atkin dissenting, refused to grant a new trial, and dismissed the plaintiff's appeal. In the House of Lords Lord Haldane delivered a judgment of considerable importance, in which he reviewed at length the evidence given and the law governing such cases. In holding that there was no evidence to go to the jury that the respondent Griffiths, empowered by the Lord Chancellor to sign orders in the case of pauper lunatics, or the defendant Anklesaria had failed to observe the law, Lord Haldane pointed out that their lordships were not trying the question whether the appellant was actually of unsound mind at the time of the inquiry, but the different question whether, on the facts as they stood, there was want of reasonable care in coming to the conclusion expressed in the certificate and the reception order. He had already laid stress on the fact that the justice has to act promptly in ordering the temporary care of an alleged lunatic and to be guided by consideration of the safety not only of the person in question but of the public. After referring to the Rules of the Supreme Court governing the powers of the House of Lords in such matters, Lord Haldane laid down that the question was not whether there was literally no evidence to go to the jury on the issue as to want of proper care, but whether there was none that ought reasonably to satisfy the jury that in point of fact such care was not taken. With regard to the respondent Griffiths, he added that assuming that he had actually satisfied himself, acting honestly and bona fide, in arriving at his conclusion and proceeding upon it, he had done the very thing which the statute told him to do and no further question arose. Four other Lords of Appeal, including Lord Moulton, whose regretted death has since occurred, gave judgment to the same effect as Lord Haldane.

A Dangerous Woman.

Una Hanley, 29 years of age, who was recently fined for falsely representing herself to be a registered medical practitioner, has since been sentenced to six months' imprisonment for bigamy. In marrying Mr. Hanley in 1911 she gave her name as Bowen, and her father's name as David Bowen Bowen, Gentleman. In going through the form of marriage in 1920 at a registry office, the subject of the charge of bigamy, she described herself as Margaret Patricia Crawford, M.B., B.S. London, and gave her father's name as Major-General James William Keogh, deceased. As a matter of fact she was the illegitimate daughter of a woman named Bowen. Her desire to extract profit from falsely associating herself with the medical profession was not shown for the first time when she committed bigamy. While living with her husband, and without his knowledge, she had defrauded many people, and on one occasion obtained more than £3000 from an officer with the help of a story that she was about to open a nursing home and that she was to be helped in so doing by well-known medical practitioners.

DONATIONS AND BEQUESTS.—The late Mrs. Elizabeth Alcock Scott, of Fernbank, Sandrock-road, Tunbridge Wells, has left by will £500 to the Homœopathic Hospital, Tunbridge Wells; £1000 to the Zenana Bible and Medical Mission; and £500 to Dr. Barnardo's Homes.—The residue of the estate of the late Mr. J. E. Darby, of Claygate, Surrey, will be divided among hospital charities at the discretion of the trustees in the event of the failure of certain trusts.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

MADRAS PRESIDENCY.

Medicine and the New Legislative Council.

Now that the elections of the first Legislative Council under the new reforms are complete, medicine and sanitation, which are transferred subjects, have been taken over by the Minister in charge, Mr. Ramunnarengar, who assumed office early last month. This is, perhaps, as momentous a change as any which has taken place under the Reforms Act, although it must be added that during the last five years Sir P. Rajagopala Chariar, who has vacated his membership of the Executive Council to become President of the new Legislative Chamber, has held the medical portfolio with conspicuous success. There is no doubt that a very largely increased expenditure is necessary if curative and preventive medicine are to do all that is required of them in this Presidency. It remains to be seen whether the new Legislative Council will be prepared to impose increased taxation for the raising of the money required to erect new medical colleges, new hospitals and dispensaries, and for extensive campaigns against epidemic disease. Madras Presidency, with a population of 42 millions, is at present provided with one medical college, which can accommodate only about 500 students. There are in addition four or five medical schools for the training of sub-assistant surgeons, but the total number of medical men passing out yearly is terribly inadequate for the population.

On the preventive side, the sanitary department may be scarcely said to have any existence. The Sanitary Commissioner's post is at present vacant. There are three Deputy Sanitary Commissioners, all Indians, each with a population of about 14 millions under his sanitary charge. In face of the lethargy and passive resistance of municipal councils and district boards where public health measures are concerned, it is wonderful how these Deputy Sanitary Commissioners maintain their enthusiasm. But it is not surprising that even the largest towns in the Presidency have failed to keep health officers, as their position has been just as precarious as was the case in England until security of tenure was obtained.

The Public Health Board.

Meantime the new Minister has introduced a Public Health Board for the Presidency which meets once a fortnight for the discussion of important health problems. The Minister in charge is president, and the members include the Surgeon-General (chairman), the Chief Engineer to Government, the Sanitary Commissioner, the Sanitary Engineer, and the Secretary, Local and Municipal Department of Government, when matters connected with medical research, hospital administration, or medical education are discussed the Director, King Institute, Guindy, the Superintendent, Madras General Hospital, or the Principal, Medical College, as the case may be, will attend the meeting of the Board. The Board of Health has absorbed the existing Sanitary Board and the Malaria Board. These two last had been in existence for many years in this Presidency, and whilst during the years of war their activities were curtailed, they performed useful functions, and were the first attempts to coördinate measures for the improvement of public health. The new Health Board has already met on several occasions.

Personnel of the Consultative Council.

Probably as a result of its deliberations the following communiqué was issued to the press a day or two ago: "The Ministry of Local Self-Government has appointed the undermentioned persons as members of the Consultative Council of Public Health, Madras," and then follows 21 names, including the Surgeon-General, the sanitary commissioner, the chief engineer, the sanitary engineer, the secretary, local and municipal department, the Commissioner of

Labour, and 14 non-officials. The non-official members are most of them members of the Legislative Council, and are chiefly chairmen of district and taluk boards who have practical experience of the difficulties to be faced in carrying out public health work in the mofussil. Three local doctors have also been included. Dr. W. Rama Rao is a local practitioner of long-standing and one who has interested himself for years in public health; Dr. Macphail, one of the staff of the Christina Rainy Mission Hospital, has 20 odd years' experience among the women of the Presidency; and Dr. L. Vira Singhe has been the lady superintendent of the Madras corporation child welfare scheme since its inauguration nearly four years ago. The medical profession is, therefore, strongly represented on the consultative council, and should be able to bring considerable pressure to bear when a scheme for the betterment of public health is held up because of so-called lack of funds. It is to be hoped that with these developments more money will be available for public health work, and that the educated members of the Legislative Council, &c., will try to stimulate their more ignorant fellow-men to some interest in matters of sanitation and preventive medicine generally.

Madras, Feb. 10th.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lieut. (Dental) W. E. A. Sampson to be Surgeon Lieutenant-Commander.

ROYAL ARMY MEDICAL CORPS.

Major G. W. Heron is seconded for service under the Foreign Office.

Capt. and Bt. Major J. D. Kidd relinquishes the acting rank of Major.

The undermentioned Lieutenants (temporary Captains) to be Captains: J. E. Measham, J. M. Savege, J. C. Burns, G. K. Fulton, and R. R. Evans.

E. C. Lindsey (late temporary Captain) to be temporary Captain.

Officers relinquishing their commissions:—Capt. H. D. Gardner (granted the rank of Major). Temp. Capts. E. C. Dimock (on ceasing to be employed as a Dental Surgeon), H. V. Lamb, F. M. Rorie, W. Andrew, H. Wands, and F. Cameron (retain the rank of Captain). Temp. Lieut. W. H. Steavenson (retains the rank of Lieutenant).

TERRITORIAL FORCE.

Major F. Loud, T.D., Sussex R.G.A. (temporary Major, R.A.M.C. T.F.), relinquishes his temporary commission in the R.A.M.C.(T.F.).

Capts. J. Taylor (late R.A.M.C., Spec. Res.), F. A. E. Crew (from 6th Battalion, Devon Regiment, and to remain attached to the Edinburgh University, O.T.C.), and V. Townrow (late R.A.M.C.) to be Captains.

Capt. H. B. Porteous relinquishes his commission in the T.F. on appointment to a permanent commission in the R.A.F.

Capt. J. R. Pooler to be Major.

Lieut. O. G. Misquith (late 24th Battalion, London Regiment) to be Lieutenant.

4th Northern General Hospital: Major E. C. Clements relinquishes his commission in the T.F. on appointment to a permanent commission in the R.A.F.

TERRITORIAL FORCE RESERVE.

Major G. L. L. Lawson resigns his commission and is granted the rank of Lieutenant-Colonel.

Capt. C. H. J. Fagan, from General List, to be Lieutenant-Colonel.

ROYAL AIR FORCE.

Medical Branch.—The undermentioned are granted permanent commissions as Flight Lieutenants, retaining their present seniority (subject to acceptance of final conditions of service): E. N. H. Gray, R. E. Bell, E. A. Lumley, D. G. Boddie, H. McW. Daniel, and A. E. Barr-Simm.

Flight Lieut. D. McLaren is granted a permanent commission, retaining his present substantive rank and seniority (subject to acceptance of final conditions of service).

Capt. (acting Major) G. Cranstoun is transferred to the unemployed list.

Dental Branch.—Capt. F. B. Stradling and W. Inman are transferred to the unemployed list.

MR. Charles Leolin Forestier-Walker, M.P., has been appointed a Commissioner (unpaid) of the Board of Control in the place of Sir W. H. Dickinson.

LITERARY INTELLIGENCE.—Messrs. Kegan Paul and Co. announce, by Miss Barbara Low, whose outline of the Freudian theory was well received, "The Gift of Psycho-Analysis to Education," a work dealing with the bearing of psycho-analysis on general educational problems.

Correspondence.

"Audi alteram partem."

A CONTROLLED STUDY OF SANATORIUM RESULTS.

To the Editor of THE LANCET.

SIR,—Dr. E. Ward's paper on this subject in your issue of March 12th contains so much that is contrary to the facts of experience that it should not be allowed to pass without criticism, for it is only too evident that unfortunate sufferers from tuberculosis at the present time have not only to fight against a grave malady, but also to struggle along in many areas without the wise judgment of a wide experience to aid them. The gist of Dr. Ward's conclusions is that better results are obtained in cases of pulmonary tuberculosis by the giving of "advice, by treatment at home, or by supervision at a dispensary, than by sanatorium treatment." Now sanatorium treatment may be defined as the best that can be done for a tuberculous patient under the best conditions by a physician who is devoting his whole time to the study of the disease; and if that is not infinitely superior to treatment elsewhere it would follow that the sanatorium physician must be a "mental defective." Yet Dr. Ward has come to the remarkable conclusion, and supported it by statistics, that after the lapse of four years 54 per cent. of patients in Stage I. who have not received sanatorium treatment are "cured," and only 31 per cent. of those who have undergone this special treatment. The former percentage would lead a casual reader to look upon pulmonary tuberculosis as a comparatively benign disease, but the experience of former generations did not give any ground for such an opinion; and while it may be said that the National Health Insurance Act provisions advanced the opportunity of treatment for the mass of tuberculous patients by ten years, I am not aware that it lessened the virulence of the tubercle bacillus. I have never previously come across any statement of figures by a reputable clinician of special experience which made any approach to the claim by Dr. Ward for the results of non-specialised treatment. When statistics lead to an absurd conclusion the compiler of them should really give pause. From the statement that "patients who left the sanatorium under a month are counted as controls," it may be deduced that those who remained in the institution for two months—or little more—were included among the results, and if so, the poverty of the latter can be understood; for a limited period of treatment in a case which would require a 12 months' residence could not be expected to lead to any permanent benefit. In any statement of results cases in a comparatively early stage should be separated from those in which there is little or no prospect of securing arrest of the disease, the former being classified as the results of "sanatorium" and the latter as those of "hospital" treatment: the sanatorium expert being in the best position from close observation to judge of the prognosis. Among the fallacies which Dr. Ward enunciates attention might be called to the statement that ex-sanatorium patients "lose ground so rapidly that after two years they have frequently fallen below the level they would then have reached had they never been in a sanatorium"; for this implies a prescience on Dr. Ward's part which is beyond understanding. The argument he employs, that "had some patients been left at work instead of being removed to a sanatorium for a few months they might have continued the running fight indefinitely," would almost lead one to despair of the effort to secure the arrest of tuberculous disease. The suggestion to allow a patient to continue at work "though far from well" displays an entire failure to realise the serious nature of tuberculous disease, and only a pessimistic attitude towards beneficent sanatorium treatment could account for it.

Dr. Ward damns sanatorium treatment with the faintest of praise, and as far as one can judge from his paper, his attitude is due to the fact that he does not realise the length of residence in an institution which the stage of disease in a particular patient necessitates. He appears to imply in one place that as this form of institutional treatment is baneful, the less of it a patient submits to the better; for he writes sarcastically: "Possibly if patients were kept at the institutions for a year or more, we should then have our authorities urging for a period of three to five years instead of one." An indefinite stay in a sanatorium or hospital would produce some surprising results; and if Dr. Ward had observed, as I have, a patient in Stage III. with T.B. in sputum reach a condition of complete arrest after a three years' residence and regain his capacity to work as a teacher for two and a half years (with every prospect of continuance), his opinion of the value of sanatorium treatment might rise. It is surprising, in contrast with the general tone of Dr. Ward's paper, to find towards its conclusion the suggestion that "a patient while at the sanatorium would stay indefinitely, the longer the better"; indeed, one would think that another hand had penned the words, for, if he accepts his own statistics, it would be much better to save the expense of sanatoriums and to treat patients "by advice only for the most part, under their own doctor, or not at all, except (by footnote) as dispensary out-patients." From experience in general practice, from attempts by myself to carry out treatment in private on sanatorium lines, and from 20 years' close association with patients in sanatoriums, I have formed a totally different opinion from Dr. Ward, and it is that other treatment of pulmonary tuberculosis stands to sanatorium treatment somewhat in the relation that moonlight does to sunlight.—I am, Sir, yours faithfully,

THOMPSON CAMPBELL, M.D.,
Medical Superintendent, West Riding County
March 12th, 1921. Sanatorium, Ilkley.

THE PELLAGRA OUTBREAK IN EGYPT.

To the Editor of THE LANCET.

SIR,—As I presume that Professor W. H. Wilson's letter[1] completes the series of criticisms which my article on pellagra in THE LANCET of May 8th, 1920, has prompted, I venture to offer a short collective reply.

While agreeing with the first of my critics, Dr. H. M. Woodcock,[2] that the origin of pellagra cannot be solely explained on a dietetic basis, I cannot subscribe to the hypothesis that the *Ascaris lumbricoides* has any ætiological bearing on this subject. In the routine performance of numerous autopsies on pellagrins neither Dr. Manson-Bahr nor myself were able to establish the invariable presence of these helminths in the intestinal canal. With regard to my other critics, Dr. J. Goldberger,[3] Professors Wilson and Lelean,[4] who deal with the subject on similar lines, I confess that their objections, though not insuperable, cannot be so easily dismissed.

However, I must agree with my friend and colleague, Dr. A. D. Bigland,[5] that the view put forward by Dr. Goldberger that the prisoners did not partake of the diet provided is an untenable one. At least, I am quite sure that they ate the hospital diet which was stated to have been supplied. Of course, I cannot vouch for the accuracy of the camp diet, which I extracted from the Report of the Committee of Inquiry on Pellagra among Prisoners of War.[6] With reference to the canteen extras of that diet, Professor Wilson states that the prisoners had not enough money to purchase them, while Professor Lelean expressed himself in his letter thus: "Careful investigation showed that practically the whole of the 2*s.* supplied to the Germans passed through the canteen accounts, &c." But apart from these canteen extras the B.P.V. (biological protein value) of their diet, even according to the report, was deemed adequate.

Now the principal blot on my "escutcheon" rests in the occurrence of two cases of scurvy among these German pellagrins. Admittedly scurvy is a food deficiency disease, and its presence in even two cases only is naturally suggestive that some deficiency might also have been operative in the coincident pellagra. With all due respect to my critics who reason in this manner, I humbly submit that the deduction is quite erroneous. In the recent well-known examples of voluntarily enforced abstention from food I believe that symptoms of scurvy were observed, but I have not heard of any reference to the onset of pellagra. Of course, I make this statement without official knowledge on the subject. At all events, I can still see no reason for not believing that the German pellagrins did not—except for the canteen extras mentioned by Professor Wilson—actually eat the diets which I originally detailed. Undoubtedly, they did not all derive the same value from them, as in addition to the variations in the powers of assimilation in normal individuals must be added the lowered assimilation consequent on debilitating diseases. I fail to appreciate the relevancy of Professor Lelean's allusion to my "missing the cardinal essentials underlying the word 'relative' applied in our report to food deficiency."

Professor Lelean juggles with calories and B.P.V.'s as if they were ponderable entities. Who can say that the nutrition of the body is so "nicely calculated less or more"? Contrast the diet of an Eskimo with that of a Hindu. Why did not pellagra occur among the British or Allied prisoners of war in Germany, Asia Minor, or Bulgaria? None of my critics have satisfactorily answered this apparent anomaly. We are all familiar with the terrible plight of the British garrison of Kut-el-Amara, and yet there is so far no record of a disease resembling pellagra having been observed among them. I assume that there is no reason to suppose that the B.P.V. of their diet approached even by a long distance the last figure of 52 given by Professor Wilson. The association of extensive damage to the intestinal tissues with the appearance of pellagrous symptoms as an argument in favour of the protein-deficiency theory has never appealed to me as convincing. Is one to assume that the incidence of dysentery in the Southern United States was greater than that among the British troops in the East during the war? This certainly cannot be the case. Nor is there any reason to suppose that the incidence of intestinal disease among the German troops was any greater than among our own. Finally, I ask if pellagra has been observed in those who have subjected themselves to a voluntary abstention from all forms of food, as in the recent instances of political prisoners.

It appears to me, Sir, that until all these apparent anomalies can be satisfactorily explained, the protein deficiency theory as the main ætiological factor in pellagra cannot be accepted.

I am, Sir, yours faithfully,
J. I. ENRIGHT.

*** Dr. Enright writes in a covering letter: "From your annotation entitled Recent Researches on Pellagra in Egypt of Jan. 22nd I glean that the conclusions of the recent R.A.M.C. committee[7] appointed to investigate the pellagra outbreak in Egypt are not in accord with those of the previous committee, presided over by Professor Lelean and Colonel Boyd, A.M.S.,[8] and are confirmatory of the opinions which I expressed on the rôle of the food deficiency factor in my original article."—ED. L.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—Contributors to the discussion on referred pain now appearing in your columns have overlooked certain points. Reflex visceral symptomatology is divisible into two parts; the first part relates to spasm of

visceral muscle, the second to conditions affecting investments and mesenteries of organs and subserosæ of their containing serous sacs. Unless spasm occur in the muscular tunic, or unless outlying structures are involved in the visceral lesion, visceral disease of grave import may remain undiscovered. Viscera themselves are innervated from segmentary centres of the cord, often far distant from sources whence their investments derive their central neuronic supply, consequently viscero-sensory impressions from an affected organ are felt in one zonal region, while viscero-sensory impressions, from investments of the same organ, are manifested at another place.

For instance, viscero-sensory impressions from muscular tunics of stomach and duodenum follow the track laid down by great splanchnic strands, and their deflections on the spinal system are manifested as referred pain and algesia at points of outcrop and at terminals of upper intercostal nerves, as witness so-called hepar or shoulder liver pain, described with much accuracy by John Hilton in his lectures upon "Rest and Pain." Whereas when gastric or duodenal ulcerations invade investments of these organs or encroach upon their peritoneal coverings viscero-sensory impressions are felt in epigastric or in hypochondriac regions.

I give only a single example, but it is sufficiently illustrative to explain differences which too frequently divide authoritative opinion upon the reliability of new methods of clinical research in the differential diagnosis of visceral disease.

I am, Sir, yours faithfully,

H. WALTER VERDON, F.R.C.S.

THE FULL USE OF ARTIFICIAL LIMBS.

To the Editor of THE LANCET.

SIR,—Your annotation of March 5th referring to Dr. M. Dockrell's letter is of the greatest interest to those who have lost limbs, and holds out hope that medical opinion is awakening to the fact that muscle training and education of the senses are all-important and indeed imperative to those who have lost limbs before they can return to a normal existence. My personal experience is a thigh amputation, of which I believe there are thousands. The limb-makers are perfectly frank, and there is no disguise that as regards war cases the aim and object of the authorities was to clear the limb hospitals and to send home the men as soon as possible with the best limb available at the time; and of all the mechanical appliances invented the central knee-control with harness over the shoulders was the simplest to avoid the use of muscles, wasted by weeks in bed, and to give a certain amount of confidence to men who had got to regain their balance. Speaking from personal experience since 1916, and quoting from an experience of over 20 years, I know that a mechanical knee worked from the shoulder is entirely unnecessary, and that with a light, well-fitting limb the stump and the stump muscles can develop an easy natural walk with perfect balance, and that the benefit to the general health of the patient is tremendous. Freedom from harness over the chest and shoulders, freedom from mechanical aid is something, but the very fact that the muscles must be developed normally and brought into daily use means much more. The system of training you mention varies with each case, and where one man whose stump muscles had been trained during the period his limb was being made was perfectly ready to go home three days after his limb was fitted, another who had acquired bad habits and a flexed stump required several weeks of careful supervision, though many of the exercises can be carried out at home. An occasional case may require only eight or nine days, some two or three weeks, while a few may require as much as three months. The greater number of men whom I have met have received little or no instruction, and that is why they rise up on the good toe and sling the artificial limb along anyhow, rising and sinking with each step. Many of them are on crutches or pegs, some to this day because they cannot drag 8 lb. along with a short stump. Quoting from one of the ex-Service societies, a number in the streets like a bit of sympathy and prefer not to wear a limb, but I believe firmly that if it was once brought home to them that they could quite simply return to nearly all their pre-war activity they would never ask for sympathy. It has been my privilege lately to help out of my experience a case that had not walked more than half a mile for ten years. A light limb was obtained, a short course of training undergone, and to quote the patient, "What it means to find that one can walk normally, to get to the shops, and carry out household duties, and, above all, to have the use of both hands, because no stick or crutch is necessary, is beyond words." The surgeons in charge of limb hospitals have no time, naturally, but if the need of training were once established there could be no better way of finding employment for some of our disabled men than in making them efficient and in establishing them in the limb centres as trainers of all those who need it.

I am, Sir, yours faithfully,

GEORGE A. PONSONBY.

Wellington Club, S.W., March 12th, 1921.

THE LABELLING OF THYROID TABLETS.

To the Editor of THE LANCET.

SIR,—We have read with great interest Dr. A. E. Carver's letter in your issue of March 12th, and we desire to say that we agree with every word of it. In the early days of thyroid medication our own practice in the matter of labelling thyroid gland tablets was based on the content of desiccated thyroid—i.e., a tablet containing 1 gr. of desiccated thyroid was labelled "1 grain," with the statement that this was equivalent to 5 gr. of the fresh gland. Later we found that there was much misunderstanding as to the dosage and nomenclature of thyroid, and on making inquiries of a number of prescribers as to what they meant when they wrote "Tab. thyroid 1 grain" we found that, without exception, every doctor consulted by us meant 1 gr. of the fresh thyroid, or 1/5 gr. of the desiccated gland. In view of the importance attached to dosage of a potent drug like thyroid, it was felt that if any doubt existed as to the doctor's intention it was safer to err on the side of giving too small, rather than too large, a dose, and, hence, our practice was reversed and our labels altered accordingly. The labels now read thus: "Compressed Tablets Thyroids. Each tablet represents 1 grain of fresh thyroid gland equal to 1/5 grain of Thyroideum siccum B.P.," and medical men who see our labels, or who read our literature, can be under no illusion as to the actual thyroid content of any tablet.

Our experience suggests that writers, and possibly teachers, fail to make clear the distinction between fresh and dried thyroids. It would undoubtedly be better were one rule universally adopted, but in view of the fact that some generations of medical men think in terms of the fresh gland only, it will be difficult to induce them to alter their practice, and the question for manufacturers is how best to carry out the intentions of the prescriber. It has also to be borne in mind that the Pharmacopœia designation is "thyroideum siccum," and where a prescriber writes "thyroid" only, no one can say that it is wrong to give the fresh thyroid. Obviously, when a prescriber writes "thyroid extract" a tablet representing the B.P. substance should be dispensed.—We are, Sir, yours faithfully,

March 15th, 1921. PARKE, DAVIS AND CO.

AS OTHERS SEE US.

To the Editor of THE LANCET.

SIR,—The letter from my old and long lost-sight-of friend, Dr. Wilson Parry, shows a misunderstanding of the point which my previous contribution was intended to make. I certainly have no personal reason to complain of the lack of "worship" among the town wage-earners; rather the reverse. But what disturbs me is that, by the bulk of working people with whom I come in contact, I am regarded as an exception in appearing to possess any public spirit at all. It was not the attitude of the public of which I complained, but the increasing justification for that attitude afforded by our public manifestations. It was the beam in our own eye to which I referred. The original title of my communication, "The Cad in Medicine," would perhaps have prevented Dr. Parry from misinterpreting my meaning. If we all approached our work in the spirit with which he approaches his, we should hold a very different place in the public mind from that which we actually do occupy at the present time.

Dr. Laing Gordon's letter in your last issue suggests the one direction in which we may look with hope.

I am, Sir, yours faithfully,
HARRY ROBERTS.

Harford-street, Stepney, March 12th, 1921.

DANGEROUS DRUGS ACT, 1920.

To the Editor of THE LANCET.

SIR,—As one of the nameless 6000 medical and dental practitioners "represented" by the London and Counties Medical Protection Society, Ltd., as a subscriber to it for some 20 years, and, moreover, a believer that its Council intends to act in the best interests of the profession, I nevertheless suggest that Dr. Hugh Woods may be mistaken if his letter appearing in your columns on March 12th intends to imply that his Council voices the medical opinions of the society's contributors, inasmuch as they are not in any way consulted.

I am, Sir, yours faithfully,
A MEMBER.

March 15th, 1921.

URBAN VITAL STATISTICS.

(*Week ended March 12th, 1921.*)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18¼ million persons, the annual rate of mortality, which had been 15·4, 15·5, and 15·2 in the three preceding weeks, was again 15·2 per 1000. In London, with a population of 4½ million persons, the death-rate was 15·1, or 0·3 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 4·9 in Swindon, 8·5 in Bootle and in Dewsbury, and 9·1 in Bournemouth, to 22·4 in Aberdare, 22·5 in Middlesbrough, and 23·3 in Tynemouth. The principal epidemic diseases caused 231 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 76 from infantile diarrhœa, 68 from diphtheria, 41 from whooping-cough, 25 from measles, 18 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 2·5 in Stockton-on-Tees, and diphtheria of 1·8 in Tottenham. The deaths from influenza, which had increased from 61 to 167 in the five preceding weeks, declined to 149, and included 27 in London, 10 in Sheffield, 9 in Leicester, 6 in Birmingham, and 5 in Hastings. There were 3730 cases of scarlet fever and 2818 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3738 and 2809 respectively at the end of the previous week. During the week ended March 5th 6 cases of encephalitis lethargica were notified in the County of London, and comprised 1 each in Camberwell, Hampstead, Kensington, Lewisham, Paddington, and St. Pancras. The causes of 32 of the 5392 deaths in the 96 towns were uncertified, of which 6 were registered in Birmingham, and 3 each in London and Manchester.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had been 18·2, 19·4, and 18·0 in the three preceding weeks, rose to 18·5 per 1000. The 407 deaths in Glasgow corresponded to an annual rate of 19·3 per 1000, and included 32 from whooping-cough, 17 from influenza, 7 from infantile diarrhœa, 3 from diphtheria, 2 each from enteric fever and measles, and 1 from scarlet fever. The 160 deaths in Edinburgh were equal to a rate of 18·7 per 1000, and included 5 from influenza, 4 each from measles and diphtheria, 3 from whooping-cough, and 1 from infantile diarrhœa.

Irish Towns.—The 147 deaths in Dublin corresponded to an annual rate of 18·1, or 0·8 per 1000 below that recorded in the previous week, and included 6 from influenza, 3 from infantile diarrhœa, 2 from diphtheria, and 1 from whooping-cough. The 161 deaths in Belfast were equal to a rate of 20·0 per 1000, and included 11 from whooping-cough, 3 each from infantile diarrhœa and influenza, 2 from enteric fever, and 1 each from measles, scarlet fever, and diphtheria.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Opposition to New Drug Regulations.

A MEETING of some 150 Members of Parliament was held in Committee Room 10 at the House of Commons on Wednesday, March 9th, to hear the views of the medical profession, the Pharmaceutical Society, and others in opposition to the Regulations proposed to be made by the Home Secretary under the Dangerous Drugs Act. Sir HENRY CRAIK, M.P., presided, and he was supported by Dr. A. COX, medical secretary, British Medical Association; Sir WILLIAM GLYN-JONES, secretary, Pharmaceutical Society of Great Britain; Mr. A. V. ALEXANDER, secretary, Parliamentary Committee of the Coöperative Congress; Mr. J. E. CONNOR, President, Pharmaceutical Society of Ireland; Mr. WALTER MCNAB, Vice-chairman, Scottish Pharmaceutical Federation; Mr. J. KEALL, President of the Retail Pharmacists' Union; Mr. WOOLCOCK, M.P., and Mr. KILEY, M.P.

The CHAIRMAN said he understood that the purpose of the meeting was inquiry rather than protest at the moment. Although the Regulations in regard to the sale of dangerous drugs were quite ripe for publication, they had not yet been submitted to the House of Commons. The Home Secretary had now stated in reply to a Parliamentary question: "I have decided to appoint a small Committee, including one or two Members of the House and a representative of the Home Office as suggested by Mr. WOOLCOCK, to consider and report to me in cases in which we have not been able to come to an agreement with interested parties what further modifications, if any, can safely and properly be made in the Draft Regulations, having regard to the main principles on which the Regulations are based, and which are essential in the public interest for safeguarding the use of the drugs." Sir HENRY CRAIK, said he thought that reply indicated that they had made some impression.

Sir WILLIAM GLYN-JONES then made a statement to the meeting. He pointed out that amongst the measures this country was committed to take under the International Opium Convention of 1912 were "to require persons manufacturing, selling, or using morphine, cocaine, and their salts to enter in their books the quantities manufactured, imports, sales, and all other distribution and exports of the said drugs," but the following significant words were added, "this rule shall not necessarily apply to medical prescriptions and to sales by duly authorised chemists." Having traced the progress of the recent negotiations with the Home Office in regard to the regulations to be made under the Dangerous Drugs Act passed last year, Sir WILLIAM GLYN-JONES said they could not accept as a reasonable explanation of the alarmingly unsuitable character of the Draft Regulations that they were only put up to be shot at. Had it not been for the intervention of the various societies interested, the Regulations as drafted would have been made operative in due course. They realised that Members of the House of Commons shared with their constituents a growing dislike of legislation by Regulation and Orders. Nothing but the most powerful reasons could justify the House of Commons deputing to a Government department the duty of legislating. The Draft Regulations were ill-conceived and badly drafted. Their publication caused grave concern to the medical, dental, and allied professions, and to the agricultural interests. They bore on their face convincing evidence that the Home Office were without the knowledge of the conditions surrounding the supply of the substances dealt with, or that the Regulations were prepared with a deliberate disregard of those conditions. They asked with great confidence that the House of Commons should insist that before making the Regulations the Home Office should take the steps, the necessity for which was the only justification for Parliament in this case deputing their legislative powers to the Home Office. They approached Members on behalf of constituents, highly trained and qualified, whose function it was to prescribe and dispense these substances. They represented those who regarded as a trust from the State the duty of protecting the public from the misuse of drugs, and they felt aggrieved that the Home Office did not welcome their suggestion. This was based on intimate knowledge of the difficulties, and was to the effect that the Home Office should have the assistance of an expert committee to whose judgment detailed suggestions could be submitted. Whether intentionally or otherwise, the attitude of the Home Office suggested an attitude of suspicion. Such an attitude might have been justified if there had been any ground to suppose that they were no
anxious as the Home Office to do everything in their
to assist the Government in carrying out any obli
they might have under the Opium Convention and of
all possible measures to prevent the formation
cocaine and opium habit, or any other misuse of th

in question. The methods hitherto adopted were those which were tried in vain by our late enemies—namely, an attempt to isolate the allies each in turn. The mistake of treating them as enemies andnot as friends of measures calculated to prevent drugging they regarded as far from complimentary. They submitted that their request all along had been a simple, straightforward, and businesslike one, and it was with great regret that the persistent refusal of the Home Office to grant it had rendered it necessary that they should trouble Parliament at this stage. The necessity having arisen they had every confidence in leaving the matter in the hands of the House of Commons.

Dr. ALFRED COX said the medical profession were not satisfied with the Regulations.

Dr. NATHAN RAW, M.P., moved:—

> "That this meeting agrees to take all possible steps to secure the fullest consultation and consideration before the Dangerous Drugs Act Regulations are made, and appoints a small committee to watch the matter and report; and in the opinion of this meeting any committee appointed by the Home Secretary should have wide terms of reference, and should be empowered to hear any evidence submitted to them on any matter affected by the Regulations, and should be sufficiently large to be fully representative."

Mr. A. M. SAMUEL, M.P., seconded the motion, which was supported by Mr. KILEY, and carried unanimously.

The following were appointed the members of the committee: Mr. J. HINDS, Sir HENRY CRAIK, Dr. RAW, Mr. ORMSBY-GORE, Sir J. BUTCHER, Mr. WOOLCOCK, Sir RICHARD WINFREY, Mr. WATERSON, Dr. MURRAY, and Mr. KILEY.

A Home Office Committee on the Regulations.

The Home Secretary has appointed a Committee to consider outstanding objections to the Regulations under the Dangerous Drugs Act, and to advise what modifications can safely and properly be made, having regard to the main principles on which the Regulations are based, and which are essential in the public interest for safeguarding the use of the drugs.

The Committee is constituted as follows: Mr. CHESTER JONES (Chairman), Sir MALCOLM DELEVINGNE, Captain W. E. ELLIOT, M.P., Major A. C. FARQUHARSON, M.P., Mr. GERALD A. FRANCE, M.P., and Mr. W. J. U. WOOLCOCK, M.P. The Secretary of the Committee is Mr. A. H. ANDERSON, of the Home Office.

HOUSE OF LORDS.

WEDNESDAY, MARCH 9TH.

Criminal Law Amendment Bill.

The Bishop of LONDON, in moving the second reading of the Criminal Law Amendment Bill, said in seeking for the third time to amend the criminal law his motive was to deal with a great and growing evil. Altogether he had received about 80 resolutions in favour of the measure from members of every denomination. He had left out of the present measure the compulsory detention of young girls in homes against their will. He had also left out the clause for the protection of boys because it was felt that no father would prosecute a woman of 21 or even older for misleading his son of 17. The age-limit of 18 in last year's Bill had been reduced to 17. Their lordships would be horrified if they could see some of the Salvation Army and Church Army homes full of children who had been indecently assaulted. The horrible idea of some men was that they could get rid of venereal disease by assaulting an innocent child. The Bill said that between the ages of 13 and 16 a child was incapable of consenting. It was provided that reasonable cause to believe that a girl was of or above the age of 17 should not be a defence. The time-limit was increased from 6 months to 12 months. The right reverend prelate gave figures to show the fearful extent of the evil of venereal disease, and said that it was the prostitution of young girls which was at the bottom of the whole thing. The societies for combating that disease with which Lord Willoughby de Broke and Lord Sydenham were associated had failed in their methods because they had not the courage to go to the real source. He would quote from a document which was not public yet, a report on the condition of London by two of the greatest authorities. This showed that in the clinics of London—and it should be remembered that only about one-tenth of the cases went to these clinics—there were 27,364 new cases in 1919 and 298,066 attendances. In the first half of 1920 there were 15,797 new cases and 214,659 attendances. At the London Hospital Clinic the numbers had increased from 658 new patients in 1918 to 1452 new cases in 1920. These medical authorities went on to report in their most interesting and careful summary that a large percentage of the patients were quite young—from 16 to 20 years of age.

The Earl of ONSLOW, Civil Lord of the Admiralty, said that the Government had hoped that the labours of the Select Committee would have resulted in a non-controversial measure, but it was clear that there were considerable divergences of opinion, especially regarding venereal disease and indecent advertisements. Although the Government left the matter to the unfettered judgment of the House they viewed the progress of the measure sympathetically. If it were passed by their lordships without material amendment the possibility of giving further facilities for its progress in the House of Commons would be considered. But in view of the pressure on Parliamentary time he could not give an undertaking that it would be possible to secure the passage of the Bill in the present session.

Lord PHILLIMORE said every form of protest should be made against the present state of immorality and he was quite content that some Bill such as this should pass. But he warned their lordships that if they took away the defence of "reasonable grounds to believe," and raised the age to 17, they would do in many cases much injustice and much hardship.

The Earl of MALMESBURY hoped that while their lordships would give the Bill a second reading they would support an amendment in Committee reducing the age of consent to 16.

Lord COLERIDGE said he thought that on the whole it would not be an unwise thing to raise the age to 17, but if they also deleted the defence of reasonable ground for belief they will go beyond public opinion and the law would break in their hands.

Viscount CAVE said he would rather have a clean-cut, retain the age of 16, and abolish the defence of reasonable belief than raise the age and leave the defence standing.

The Earl of DESART said the Bill would involve the danger of very great injustice.

Lord WILLOUGHBY DE BROKE said he was going to vote for the second reading of the Bill, but the right reverend prelate must not imagine that he had disposed of the arguments which he would venture to offer in reference to venereal disease.

Joint Responsibility of the Sexes.

Lord DAWSON OF PENN said when he put the evils on the one side and the Bill on the other he could not see that the measure was going to succeed in removing the evils they all so greatly desired to remove. He did not say that the Bill was not a good one, although he thought there were certain respects in which it was liable, quite unconsciously, to do evil. They needed to distinguish between the sexual instinct which was based on nature and the sexual instinct which was unnatural and perverted. Cases of older offenders, men and women, defiling young boys and girls could not be dropped upon with too heavy a hand; but Clause 1 seemed to him to include the possibility and perhaps the probability of sometimes bringing within its meshes the young, possibly a boy of 18, who was accused of defiling a girl of 16 or 15. An offence against such people was on an entirely different footing. That was a natural instinct which had overflowed its banks at an age at which restraint was deficient, and it seemed to him deplorable that young persons under the age of 18 should be liable to the criminal law for offences of that description. Such young people did not require the dock; they rather required education, uplifting and moral suasion. Some proviso should be inserted which would place the younger offender on a different footing from the older offender. When the legislature extended the age for carnal knowledge to 16 it did so because it took the view that a young person of 16 was too immature either to form a judgment or be what he would call a conscious and even instigating sexual agent. But when the age of 16 was passed the changes which took place in the girl were often very rapid, very capricious, and very marked. The girl was unlike the male. The male would develop steadily; the girl would often develop by leaps and bounds, and in the course even of three or four months she would pass from girlhood into apparent womanhood. And when that occurred it was extraordinarily difficult to tell her age. It would be quite easy to select five or six girls of the age of 17 in whom one could represent by appearance any age from 15 to 21. With a girl's quick development after 16 she became a conscious sexual agent. She might be more than that; she might become an intentional sexual instigating agent. That was where his difficulty lay in the raising of the age. He was as anxious as anyone to give all the protection that could be granted, but the very moment that the girl became a conscious and often an intentional instigating agent it seemed to him extraordinarily difficult to throw the whole blame for sexual misdoing on the man. It was a curious commentary to his mind that the large body of public opinion that was constantly maintaining that there should be an equal standard of responsibility for the two sexes—a view with which he had considerable sympathy—should now be willing to protect the girl at the expense of the man, and put the man on an inequality as compared with the girl. It did not seem to be right or fair, or likely to lead to the public good to throw the whole onus on the man. He was not concerned with the older man. The older man of 25 and upwards had developed a certain amount of stability. But take the example of a young man coming up to London for pleasure. He came up with innocent intentions but full of the impetuosity of youth. Supposing he happened to meet a precocious girl of the age of 16½ years, who might perfectly easily look 18, and who is accustomed to sexual intercourse. Notoriously, a young man was a bad judge of age. The girl formed an attraction for the youth. What did she do? She set to work to throw allurement after allurement over him. She used all the artifices of her sex to achieve her object. She gradually saw him being lashed into the elemental and aggressive male, and when that point was reached he was like a runaway horse; his control had gone. He pursued and he succumbed. It might be asserted, in that particular instance, that the more experienced and semi-professional girl was far more to blame than the youth. But she got off scot-free, while you converted him into a criminal and ruined his career. He was not going to contend that all the cases fell into that category, but those were his reasons for doubting whether it was wise, or possible, to raise the age to 17. There was another point of view which was of considerable importance, and which made one hesitate before placing responsibility for sexual intercourse exclusively on the male. Certain physical realities of life seemed to have been almost entirely ignored by many earnest social reformers. Sex attraction is one of the elemental things of life, and it would be agreed in regard to the instincts which moved men and women in sex matters the first outstanding instinct of the male was pursuit. It might be checked, and should be checked in civilised society, by moral and religious ideas; but there was the elemental instinct. The instinct of the female was resistance, reserve, followed, if she is won, by surrender. That instinct of reserve and resistance on the part of the female was the physical basis of woman's modesty, which was the most potent individual force that made for sexual morality in a community. There was no force which could adequately take its place. The second point was that the sexual desire of the woman was much more conditional than it was with the man. The average woman had to love before she had passion, or at any rate she had slowly to develop a strong liking for a particular individual before her passion was aroused. She had none of the promiscuous qualities of the male and, unconsciously or consciously, her sex instinct was associated with maternity. She was therefore much more protected by nature than the male. That must be taken into account when they were dealing with the borderland age between 16 and 17. They must do one of two things: either they must leave the age where it was, or they must make both male and female responsible before the law for illicit sexual intercourse.

The Widening Basis of Promiscuous Intercourse.

On the question of brothels, Lord Dawson said: I entirely agree with everything that the right reverend prelate has said. But, like a clever advocate, he carefully described a brothel of a particular type. What seems to me to be the true and proper description of a brothel is a place where the proprietor farms the earnings of the girls who resort there. That class of brothel, where the girls either live or resort, where their earnings are either handed to the proprietor, or the proprietor takes toll directly from the patrons, is a brothel according to the more strict conception of that word. And I cannot understand anybody disagreeing with any sort of provision which would lay the heaviest possible hand on such institutions. But we have to be cognisant of this—that according to legal practice, as I understand it, the word "brothel" has a very much wider application than the one which the right reverend prelate described. It is so wide that any place where women resort for promiscuous intercourse, however well conducted or ordered it may be, can be brought within the definition of a brothel. And so it arises that you may even have an hotel which is conducted in an orderly way where women resort, not always with the same men, for promiscuous intercourse, and that hotel can be brought within the arms of the law. Here, again, I feel doubts. It is always a serious thing to try to repress a manifestation of a disease unless you can reach its cause. And one of the most grave aspects, in my humble opinion, of the sexual evil of to-day is the widening of the base of promiscuous intercourse. And that widening of the base of promiscuous intercourse was not the result of the war, though, no doubt, it was aggravated by the war. It was obviously beginning to occur several years before the war, and, though it may be true that sentimental promiscuous intercourse with an amateur is less offensive to one's taste than promiscuous intercourse which is entirely bought from the professional prostitute, yet, viewed from the point of view of the interest of the State and the good of society, I am inclined to think that more harm is done to society by the amateur than by the professional prostitute. And when one sees the base of promiscuous intercourse being steadily widened, does not it make one ask oneself, Is not it worth inquiring why that has taken place; is not it worth inquiring whether it would be possible to check such widening of the base of promiscuous intercourse? I am not prepared to answer that question, but I would throw out the suggestion that if you adopt a policy of too much repression of the manifestation of a disease, you drive the disease inwards, and you alter its manifestations often for the worse, and you do not cure the disease. We have promiscuous intercourse as a fact. Unless we are prepared to make it illegal we have to accept it as a fact. By all means work to reduce it and remedy it by removing the cause, but it is there, and, as long as it is there, the people who indulge in it will find some place to which they can resort. And therefore, while I entirely agree with the very heavy penalties which are suggested for the kind of brothel described by the right reverend prelate, I should deplore if the same repressive policy were adopted towards that different type of place to which I have referred. It is not that I approve of it, but people who indulge in promiscuous intercourse are going somewhere, and I am apprehensive that, if legislation is too repressive towards that hotel type of house, you will still further widen your base of promiscuous intercourse and drive it into the back rooms of restaurants, into tea-rooms, into dancing places, and even into the home. For these reasons I think one requires to have caution, however much one may wish to bring about reform. One wants to inquire in the closest possible manner whether what one seeks to decree may not possibly bring about more harm than good.

Continuing, he said that he would not like it to be felt that he was taking up the attitude of no action. On the contrary, there were provisions in the Bill which he thought one could support with confidence. But he did not believe that the problem of promiscuous intercourse was to be met by legislation, but rather by social reform and betterment, by better houses, by encouraging community life, as was exemplified in the idea of garden cities, larger recreation grounds for the people, such as they got in the public schools, and the better education of youth, by facilities for earlier marriage, the return to the larger family, and the frank recognition that if people were going to marry they must have control over the output of their offspring. On these lines reform could be looked for more hopefully than by methods of legislation.

The Bill was read a second time.

TUESDAY, MARCH 15TH.

Criminal Law Amendment Bill.

The House went into Committee on the Bishop of London's Criminal Law Amendment Bill.

On Clause 2 Lord MUIR-MACKENZIE proposed to substitute for it the following: "reasonable cause to believe that a girl was of or above the age of 16 shall not be a defence to a charge under Section 5 or 6 of the Criminal Law Amendment Act, 1845."

The Bishop of LONDON and the Government expressed their willingness to agree to the amendment and the clause of Lord Muir-Mackenzie was substituted for that in the Bill.

The Committee stage of the Bill was completed, and the Bill as amended was reported to the House.

HOUSE OF COMMONS.

TUESDAY, MARCH 8TH.

Schemes for Welfare of the Blind.

Mr. JAMES BELL asked the Minister of Health whether he had received any protests against Paragraph (d) in Circular 182, which pointed out to local authorities that it must be clearly understood that in connexion with schemes for the welfare of the blind, he would find it very difficult to sanction expenditure on new buildings, and the general tenor of which was such as to discourage local authorities in exercising their duties under the Blind Persons Act in a proper manner; and whether, in view of the inadequacy of voluntary help for the blind which resulted in the Act being passed, he would revise the paragraph in question and encourage the local authorities to incur all necessary expenditure in the interests of these helpless people.—Dr. ADDISON replied: I have so far received only one protest of the kind indicated in the question. I see no reason to withdraw the reference to the welfare of the blind from the circular referred to, seeing that the existing buildings can usually be adapted. I can assure the honourable Member that I am most anxious to promote the interests of the blind, and I feel sure that the schemes which local authorities are required under the Act to prepare and submit to me will be designed to that end.

WEDNESDAY, MARCH 9TH.

Opium for Hong-Kong.

Mr. GILBERT asked the Secretary for India whether ther
was any arrangement in operation whereby the Ind
Government supplied opium to Hong-Kong, and what w
the terms and the duration of such arrangement.
MONTAGU replied: The agreement formerly existing f
supply by the Government of India of opium to the G

ment of Hong-Kong has been renewed for a further period of five years with certain modifications. Under the new agreement, which has effect for five years from Jan. 1st, 1921, Hong-Kong will be supplied with ten chests of opium a month, at a fixed price. No obligation rests on the Government of Hong-Kong to take any prescribed minimum quantity of opium.

India and Dangerous Drugs Act.

Mr. Gilbert asked the Secretary for India whether there were any Pharmacy Acts in operation in India similar to those in this country; and whether it was proposed to introduce legislation in India similar to that of the Dangerous Drugs Act with a view to limit the use of such drugs to legitimate medical and scientific purposes.—Mr. Montagu replied: There are no Pharmacy Acts in operation in India similar to those in this country. It is not proposed to introduce legislation in India similar to the Dangerous Drugs Act, as the regulation of the traffic in, and use of, such drugs is already strictly controlled under a variety of local and Imperial Acts. I may add for the information of the honourable Member that it is believed that the law and the practice in India in respect of all such drugs are entirely in accord with the provisions of the Hague Convention. The Government of India were, however, requested some time ago to examine the whole body of law and regulations on this subject, and to effect such amendments, if any, as might be required in order to bring their law and practice into precise conformity with the provisions of the Convention.

New Tuberculosis Treatment.

Colonel Sir Arthur Holbrook asked the Minister of Health whether, in connexion with the proposed transfer of tuberculosis treatment from the health insurance committees to county and borough councils, he would make provision to secure adequate and permanent representation for the members of health insurance committees upon the new committees to be appointed.—Dr. Addison replied: I am hoping to introduce legislation on this subject shortly, and the point to which the honourable and gallant Member refers will be borne in mind.

The Spahlinger Serum.

Mr. Higham asked the Minister of Health whether, in view of the interest among the many sufferers from the disease in this country, he had sent an expert to inquire at first hand into the Spahlinger serum for the treatment of consumption; and, if not, whether he would consider the advisability of sending an expert immediately.—Dr. Addison: This question has already been carefully explored and was before the Medical Research Committee in 1914. There would be no advantage in the adoption of the course suggested, as much of the work has been done in London.—Mr. A. M. Samuel: Will the right honourable gentleman publish as much as possible about the researches into this treatment, so that those who are suffering from tuberculosis may know whether it is worth their while to pursue any further investigations on these lines or not?—Dr. Addison: I will give all the information I have, but the preparation of this material is a secret, and it is quite impossible further to explore such suggestions and give any advice on the subject without proper clinical inquiry and other experiments. Until that material is available it is quite impossible to express any opinion.—Mr. Short asked if the treatment was really successful or not.—Dr. Addison: I have already said that the material is not sufficient to express any proper opinion. I am sure honourable Members will realise how important it is not to mislead thousands of sufferers from tuberculosis by holding out any hope which may not be justified.

Wellhouse Hospital, Barnet.

Lieutenant-Colonel Fremantle asked the Minister of Health the cost to the public of the erection of the Wellhouse Hospital, Barnet; the latest figures available as to the cost of maintenance and treatment; the proportion of such cost attributable to paying patients; the amount of fees received; the number of staff engaged; and the numbers, respectively, of Poor-law patients and paying patients treated.—Dr. Addison replied: A loan of £40,000 was sanctioned for the erection of this infirmary, and £38,505 was raised by the guardians. The infirmary was only opened recently and no figures of the running costs or of the amounts recovered from persons relieved in the infirmary have as yet been returned. According to a return made by the clerk to the guardians, the staff numbers 36, and there are also two consultants. I am obtaining from the guardians the further particulars required, so far as they may be available, and I will send my honourable and gallant friend these particulars as soon as I receive them.

Insurance Committees and New Medical Records.

Mr. Bartley Denniss asked the Minister of Health ...her he had received any representation from Insurance ...ttees with regard to the new medical record cards in use for insured persons.—Dr. Addison replied: I have received representations with regard to the medical record cards from four only of the Insurance Committees, which, as my honourable friend is no doubt aware, administer medical benefit in every county and county borough. In three cases the representations are on matters of detail, and in the fourth case the committee has sent me a resolution that the keeping of the records is desirable for securing a proper medical service for the insured population. I have also received a letter from the chairman of the National Association of Insurance Committees stating that the opinion of the Executive Council of that body is that the keeping of the medical records is unquestionably in the interest of insured persons.

Death-rate of Infants.

Mr. Trevelyan Thomson asked the Minister of Health how the death-rate of infants under one year of age during 1920 compared with the recent preceding years; and whether, as a part of promoting public economy, he proposed to reduce the number of infant welfare centres and maternity beds available for this service.—Dr. Addison replied: The death-rate of infants under one year of age per 1000 births during the years 1914 to 1920 is as follows: 1914, 104·62; 1915, 109·72; 1916, 91·21; 1917, 96·5; 1918, 97·16; 1919, 89·13; and 1920, 80. The figure for 1920, which is subject to verification, is the lowest yet recorded. The answer to the second part of the question is in the negative. Mr. Thomson: In view of the extremely satisfactory results achieved by the Ministry, will the right honourable gentleman consider the desirability of circulating the information among local authorities so that they may continue this good work?—Dr. Addison: I am preparing a statement which I hope to issue to the local authorities on this matter.

Vitamines.

Major Barnett asked the Minister of Health whether any and what steps were being taken to bring to the knowledge of the public the fact that vitamines, which constituted a necessary part of any sound diet, were essential to the diet of the young, and could be secured by utilising whole cereals and whole pulses, fruits, salads, and vegetables; and whether he would publish and disseminate as soon as possible a short practical leaflet which, without advocating any special system of diet, would draw attention to the value of these wholesome and economical foods.—Dr. Addison replied: I am considering whether it would be practicable to issue any statement on this subject. Any such statement would, of course, contain as full a reference to the part played by vitamines in nutrition as the present state of knowledge of the subject would permit. The honourable and gallant Member may be interested in the treatment of this matter on pp. 177–184 of the Report of the Chief Medical Officer of the Board of Education published in 1919 (Cmd. 420).

The Treatment of Cancer.

Mr. Gilbert asked the Minister of Health whether his attention had been called to the recent increase of deaths from cancer; whether he had any committee or officers in his department who were making any inquiries into the cause of and cure for this disease; whether his department made any financial grants to any hospital or institution which was providing research work or special wards and treatment for this disease; and, if not, whether, in the interest of the community and the need of combating this scourge, he would favourably consider granting financial help to any such hospital or institution.—Dr. Addison replied: I very much regret to say that the number of deaths attributed to cancer continues to rise. My honourable friend is no doubt aware that an extensive research into the causes of the disease has for some time past been undertaken by the Imperial Cancer Research Fund, and the Medical Research Council are facilitating research into the possibilities of radiotherapy and have been the means of providing a substantial quantity of active radium salt for the purpose. Cancer research funds are relatively well supported from voluntary sources, and I do not think that the issues are sufficiently clear for me to recommend grants in aid of the cost of the treatment of this disease at the present time.

Malaria in England.

Captain Elliot asked the Minister of Health whether, in consequence of the number of men in this country who still suffered from malaria contracted abroad during the war and of the abundance of mosquitoes present in many parts of England, malaria was now occurring in the civil population; and what steps were taken to prevent the spread of this disease in mosquito-infested areas.—Dr. Addison replied: The matter referred to in the question has received the close attention of the medical officers of the Ministry. The action taken is fully described in two separately issued "Reports and Papers on Malaria Contracted in England" relating to 1917 and 1918, respectively, and in the annual report of the Chief Medical Officer for 1919-20. The policy of prevention is based primarily on securing the early detection of all cases and carriers of malaria and arranging that they are thoroughly treated with quinine, thus removing, or greatly lessening, the risk of infection if they are bitten by mosquitoes which can spread the infection. Efforts are made at the same time to protect all such cases and carriers against mosquito-bite as far as possible. Special supervision for these purposes has been arranged in the Isle of Sheppey, where most of the infection arising in England has occurred. The measures taken have greatly lessened the risk of spread. The total number of locally contracted cases reported among the civil population in England was only 32 in 1920, as compared with 93 in the previous year.

Maternity and Child Welfare.

Captain ELLIOT asked the Minister of Health what grants were made by his department to local authorities towards the cost of maternity and child-welfare work, and what proportion of the total expenditure was represented by these grants.—Dr. ADDISON replied: Grants amounting approximately to £855,000 will be made during the current financial year towards the expenditure of local authorities on maternity and child welfare. The grants represent less than ½*d.* in the £ on the total sums voted by Parliament for the supply services of the country.

THURSDAY, MARCH 10TH.

Suggested Reduction of Medical Staff.

Lieutenant-Colonel Sir JOHN NORTON-GRIFFITHS asked the Minister of Pensions whether, in order to assist demobilised soldiers, and to make further economies by reducing the number of the existing staff of medical men and others, he would arrange to allow demobilised soldiers who were in employment or starting in business to commute their pensions.—Mr. MACPHERSON replied: I am unable to accept my honourable and gallant friend's suggestion. It is not my policy, nor was it that of my predecessors, to encourage commutation of pensions, and I am convinced that to do so would be to cause many pitiable cases of destitution in the future. Final weekly allowances which are granted to soldiers who are only slightly disabled are on a somewhat different footing, and although commutation of these allowances cannot be generally permitted, it is possible for the Ministry to consider a very exceptional case where payment of a lump sum is clearly in the man's interests.

Refusal of Disability Pensions.

Mr. TREVELYAN THOMSON asked the Minister of Pensions whether, in view of the dissatisfaction caused by the refusal of pensions on the grounds that disability was alleged to be not due to war service, he would take steps to remodel the royal warrant so that any man who on discharge from the army was classified in a lower medical category than that in which he was placed on enlistment could on that account be deemed to have a prima facie case for a disability pension.—Mr. MACPHERSON replied: I am unable to accept this suggestion. Under the present practice each case is considered on its merits in the light of all the evidence available, and if the claim is rejected on the ground that the disability is not due to service the man has a right of appeal to an independent tribunal.—Mr. THOMSON: Can the right honourable gentleman infuse some of his well-known sympathy into the administration of his department in dealing with these cases?—Mr. MACPHERSON: I hope I always do so.—Mr. A. SHORT: Is the right honourable gentleman aware of the great dissatisfaction with the results of these appeals to the Appeal Tribunal, and can he explain why it is that such cases are referred to this tribunal?—Mr. MACPHERSON: The House decided that such cases were to be referred to an outside appeal tribunal. I have no responsibility for that tribunal, nor is it under my jurisdiction, but I am bound both in the interests of the pensioner and the taxpayer to accept its decisions.—Mr. SHORT: Will the right honourable gentleman make representations to the Cabinet on the matter?—Mr. MACPHERSON: I think that is for the House to do and not for me. I am myself very often a defendant in cases.

Health Precautions against Unhealthy Aliens.

Sir HARRY BRITTAIN asked the Prime Minister whether he was aware that large numbers of alien emigrants of the most unwholesome description were being regularly conveyed across England for trans-shipment to Atlantic ports; and whether, seeing that such visitors were liable to bring disease into this country, he could see his way to safeguard our own people by imposing some such regulations as existed, for example, at the port of New York.—Mr. SHORTT (Home Secretary) replied: No, Sir. I cannot accept the first paragraph as representing the facts. The aliens who pass in large numbers through the United Kingdom to America have already before their departure from the continent come under the operation of the regulations which the honourable Member has in mind. The shipping companies which carry them are liable to heavy penalties in America for every diseased alien whom they take there, and are also required by the American law to take such passengers away again. The companies are also obliged, under the terms of what are known as transmigrant bonds into which they enter with the British Government, to see that no such alien remains in this country. All this is in addition to the general precautions taken by the Ministry of Health under the Aliens Order and by port sanitary authorities against the introduction of disease into the United Kingdom.—Sir H. BRITTAIN: Who is it that examines these aliens from the Central European countries which in many cases are glad to get rid of them; and is it any satisfaction to this country; are the shipping companies that take them to the United States of America or Canada fined for taking these people there, when the damage has already been done; and lastly, may I ask, in reference to the right honourable gentleman's statement that all these things are in addition to what the sanitary and port authorities do, if these individuals walk direct from the boat to the train, what does that amount to?—Mr. SHORTT: They do not without proper examination by doctors.

Amendment of Lunacy Laws.

Mr. ALFRED DAVIES asked the Minister of Health if his attention had been drawn to a resolution passed by the committee of visitors by the Isle of Ely and Borough of Cambridge Mental Hospital; that in the opinion of the visitors the use of the terms pauper lunatic and pauper lunatic asylum should be discontinued, and that the Ministry of Health be asked to procure an amendment for the Lunacy Acts, substituting the terms patient and mental hospital; and whether, in view of this essential reform, he would give this matter his careful consideration.—Dr. ADDISON replied: I am in sympathy with the spirit of the resolution, but it would require considerable amendment of the Lunacy Acts to eliminate these terms altogether, and I am afraid that any substituted terms would tend to acquire the same associations.

Dental Legislation.

Captain WEDGWOOD BENN asked the Minister of Health if he could state when he proposed to reintroduce the Dental Bill, and what provisions it would include relating to the admission of unqualified dentists to the profession.—Dr. ADDISON replied: I am hoping to confer shortly with the various representative organisations concerned with a view to the introduction of the Bill as an agreed measure, but I am not at present in a position to name any definite date for its introduction.

FRIDAY, MARCH 11TH.

Typhus in Eastern Europe.

The House went into Committee of Supply on a supplementary vote for diplomatic and consular services, Mr. WHITLEY in the chair.

Mr. CECIL HARMSWORTH (Under Secretary for Foreign Affairs) said the question of the means that had been taken by the League of Nations to meet the situation in regard to typhus in Eastern Europe had been much in the mind of the medical world of Europe, and had been the subject of the most careful inquiry by the highest medical authorities. The matter had been the subject of a special mission sent by the League of Nations to the affected areas. All the authorities dwelt upon the devastating effects of the disease in Poland and Russia, and on the risk of its spreading to Western Europe. Finally, a report in the name of the Canadian delegate to the League of Nations was submitted to the Assembly at Geneva. The Committee stated that the epidemic condition of typhus in Poland and Galicia was very grave and constituted a distinct menace, especially to Eastern Europe and in general to the world at large; that the resources of mechanical and medical equipment of Poland, though hitherto employed in an excellent manner, were altogether insufficient successfully to cope with the conditions in Poland itself; that the infection of typhus was widely distributed in Russia and other countries adjoining Poland, and opportunities for its distribution were constantly and continually increasing; that urgent necessity existed for an immediate and adequate effort, participated in by all the nations of the world, successfully to combat a menace which was international and world-wide. At first it was proposed to proceed on a very elaborate scale, and it was estimated that a sum of not less than £3,500,000 would be required in order to institute a thoroughly satisfactory health system all along the eastern frontier between Poland and Roumania and Russia. It was, indeed, intended to establish a real *cordon sanitaire* all along this line, and appeals were
the League of Nations, but he regretted to say
met with comparatively little response. It
decided that the greater scheme must remain
and that what could be done with whatever f
got together should be done quickly. Dr.
Chief Medical Officer to the Board of Health

no less strongly than any other medical authority the need for these remedial measures. He (Mr. Harmsworth) put himself in touch with Dr. Buchanan, who had written to him as follows:—

> "The case is a very strong one. If typhus, and still more cholera, gets to be imported wholesale by the return of refugees, prisoners, &c., or by the resumption of ordinary traffic between Soviet Russia and the countries of the West, we have (*a*) constant risk of importation of infection in this country, and (*b*) serious epidemic conditions superadded to the distress, starvation, and other troubles of the parts of Central Asia which it is in everyone's interest to see settled."

Typhus, he understood, often developed a case mortality of no less than 40 per cent. The Polish Government had done everything that could reasonably be expected of it, but it was not purely a national question. In August last the Lord President of the Council was requested by the League of Nations to issue a special appeal. In the case of that appeal again it was to be regretted that the response was not as large as one could wish. Very considerable sums, however, had been voted and promised. Greece had given £10,000, Japan £5000, Switzerland £2000. The Government of Canada had promised £200,000. Persia had given £2000, Belgium £1000, and Siam £1000. France had not yet given anything. In the United States it was being considered, but it was not possible to make forward grants in anticipation of a decision of Congress. Spain had promised £40,000, Germany 1,000,000 paper marks, Holland 100,000 florins, China £2000, and Uruguay and Peru were also contributing. He thought that a sum approaching £225,000 was more or less available. As recently as January, 1919, there was a great outbreak of typhus in and about Rotterdam. From his information there were 823 cases and 100 deaths, so that even in what was acknowledged to be one of the cleanest countries in the world they had an outbreak of typhus. This work was eminently suited to the League of Nations.

Major C. LOWTHER moved to reduce the vote by £49,000. It seemed to him a tall order to call upon the taxpayers of this country to provide £50,000 for combating typhus in Poland when there was so much disease at home on which money could be spent.

Captain ELLIOT thought that Major Lowther had not fully realised the enormous value of the medical maxim that prevention was better than cure. If they could stamp out this disease at its focus they made a tremendous difference to the health of Europe, which meant the trade of our own country. Until 1900 they groped in the dark in the treatment of typhus. They thought it was due to dirt and overcrowding or famine, but they were not sure. Then they found that it was due to a louse which bit an infected man and then carried the germ to a healthy subject. One of the chief factors in spreading a typhus epidemic was the railway. The railways of South Russia had a great deal to do with the continuous spread of typhus in that country. Every train was a travelling pest-house, because on the trains travelled the lice. The man who went into one of those trains was going into a place as deadly as a den of rattle-snakes. How could they expect our traders to move freely in a country where the conditions of transport were such that a man entering a train was literally taking his life in his hands? This was not merely a Polish question, but a British question as well. This sum was in the nature of an investment. If we could extend credit for rolling-stock, cotton goods, and for rubber to these devastated countries, the extending of credit for health must be one of the most immediate and practical investments. They were quite satisfied in the medical world that this sum was being properly and efficiently expended. But they were not satisfied that there was that unity of command which was necessary for stamping out the disease. If the Under Secretary could give them an assurance on that point they would have still more pleasure in supporting him.

Sir J. D. REES repudiated the doctrine of Captain Elliot. He was sure that all the honourable Member said about typhus was perfectly true, and he realised that the healthier Europe was the better off was England. But that England should therefore sanitate all Europe was a totally different proposition. Could the British taxpayer afford these counsels of perfection?

Mr. HARMSWORTH said he would certainly look into the matter of the unity of control, and if it was thought necessary would respectfully direct the attention of the Secretary-General of the League of Nations to the representations that had been made by the House.

Dr. MURRAY said that we had practically got rid of typhus in this country, and when he heard people in that House and elsewhere grudging money for combating things of that sort he must say their zeal for economy was much misplaced. He hoped they were now laying the foundation for a great sanitary effort which would go on till this [illegible] was eradicated in Poland.

jor LOWTHER withdrew his amendment and the vote agreed to.

MONDAY, MARCH 14TH.

Medical Staff of Pensions Department.

Brigadier-General WIGAN asked the Minister of Pensions how many medical officers were employed by his department; what their daily hours of work were; how many equipped beds the Ministry had in hospitals; the number now occupied; and what the total annual cost per bed was inclusive of all charges.—Major TRYON replied: There are 325 whole-time administrative medical officers whose hours are 44 per week and 274 whole-time institutional medical officers who are employed upon no fixed hours, being liable for duty at any time. There are 251 part-time medical officers whose hours of employment average 12 weekly. Members of medical boards are drawn from a panel of 4462 doctors who are employed as required on a sessional basis. The Ministry also make use of specialists and medical referees, numbering 3616, who are paid by fee for examination and report. The number of equipped beds in hospitals is 12,976, of which 10,995 were occupied at the date of the last return. The total annual cost per bed averages £175.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on March 11th the following degrees were conferred:—

M.D.—A. G. Evans, Trinity; R. R. Walker, St. John's.
M.B. and B.Ch.—E. P. Brockman, Caius.
M.B.—R. K. Merson, Emmanuel.

UNIVERSITY OF OXFORD: *Memorial to Sir William Osler.*—The fund to establish a memorial to the late Regius professor of medicine has now reached nearly £2000 and a list of subscribers will be published soon. Subscriptions may be sent to the honorary treasurer, Mr. A. P. Dodds-Parker, 2, Holywell, Oxford.

Diploma in Public Health.—The Board of the Faculty of Medicine gives notice that at the examinations for the Diploma in Public Health in Michaelmas Term, 1921, and afterwards the first part of the examination will comprise the Application of Chemistry and Physics to General Hygiene, and General Pathology with special relation to Infectious Diseases. The second part will comprise Practical Pathology and Bacteriology, General Hygiene, the Laws relating to Public Health, Sanitary Engineering, and Vital Statistics. The Examination in Michaelmas Term, 1921, will be conducted in accordance with a timetable published in the *University Gazette* for March 9th, 1921 (Clarendon Press, Oxford, 3*d.*). The effect of this announcement is to remove from Part 2 to Part 1 the examination in Systematic Pathology and Bacteriology; but to retain in Part 2 a practical and viva voce examination in those parts of the subject which are most closely related to public health.

Degree in Medicine.—At a congregation held on March 3rd the degree of Bachelor of Medicine was conferred on Philip Geoffry Doyne, Trinity College.

Degree days.—The following Degree Days are announced: To-day (Saturday), March 19th, at 10 A.M.; April 28th, May 21st, June 16th and 23rd, and July 9th, at 2.30 P.M.

UNIVERSITY OF EDINBURGH: TAIT MEMORIAL CHAIR.—The second chair of natural philosophy, promoted as a memorial to Professor Tait, will shortly be established. The funds collected before the war have recently been augmented, and the University Court have been able to arrange for the foundation of the Tait chair not later than the year 1925.

UNIVERSITY OF GLASGOW.—On March 11th Mr. Bonar Law was formally installed as Lord Rector of Glasgow University, and thereafter delivered his rectorial address on "Ambition, and the Qualities which make it Successful." He said that in the biographies of famous men it was constantly stated that they had in their youth set before them as their ambition some position which they afterwards attained. That was true, but it was forgotten that for each realised ambition there were very many unrealised ones. Life was an uncharted ocean, and there must always be uncertainty as to what would be found at the end of the journey. Mr. Bonar Law quoted the words of Cromwell: "He goes furthest who does not know whither he is going." Great men were not so much those who foresaw events as those who seized opportunities. Foresight was certainly a quality essential to success, but the possibilities of foresight were very limited and astute foresight was much rarer than was generally supposed. When a man seized the tide that led on to fortune he had only the vaguest idea of the nature of the voyage, or of the shore upon which he would finally disembark. The qualities essential to success were courage, hard work, the wish to succeed, and the love of good work for its own sake.

UNIVERSITY OF BRISTOL.—At examinations recently held the following candidates were successful:—

SECOND EXAMINATION FOR DEGREES OF M.B., CH.B.

Part II.—Hyne Catherine Barclay, Sydney H. Blacker, Arthur P. Bodman, Naomi Joan Bown, Ernest G. Bradbeer, Gilbert B. Bush, Ernest R. Clutterbuck, William L. Cossham, Mary Frances Dalton, Helen Mary Dixon, Robert H. Dummett, Lorna Dunn, Frank R. Edbrooke, Edward B. Eedle, Norman J. England, Herbert M. Golding, William A. Gornall, John L. Griffin, Rowland C. Hatcher, Alexander G. Heron, John A. James, Frederick G. Jenkins, Doris Ewing Joscelyne, Edgar F. King, Arthur H. Marshall, John R. Nicholson-Lailey, Arthur S. Prowse, Robert A. Sammons, Arthur E. Sherwell, Herbert Taylor, Robert E. Whitby, Cicely Faith Wilson.

Anatomy only (completing Examination).—George S. Mundy.

THIRD EXAMINATION FOR DIPLOMA IN DENTAL SURGERY.

Dental Anatomy only.—Robert H. Davies, Harold C. Hopes, Kenneth A. Hunt, Edwin H. Longney, Cyril G. Payne, Herbert W. Pidgeon, Montie Ritblat, Cecil R. Woods.

ROYAL COLLEGE OF SURGEONS OF ENGLAND: NEW FELLOWS.—An ordinary Council meeting was held on March 10th, Sir Anthony Bowlby, the President, in the chair. As the result of the Final Fellowship Examination, held from Feb. 11th to 19th, 19 candidates were approved and 30 were rejected. The following are the names and medical schools of the successful applicants upon whom the Council has conferred the diploma of Fellow:—

John Alban Andrews, Edinburgh and St. Bart.'s Hosp.; Lennox Ross Broster, Oxford Univ. and Guy's Hosp.; Victor Marcus Coppleson, Sydney Univ. and London Hosp.; Henry Evers, Durham Univ.; George Philip Buckingham Huddy, London Hosp.; James Alfred Jenkins, New Zealand Univ.; Roy Russell Kerr, Edinburgh Univ. and St. Bart.'s Hosp.; John Le Messurier Kneebone, Adelaide Univ. and London Hosp.; Charles John MacAuley, Dublin Univ.; Kenneth MacCormick, New Zealand Univ. and London Hosp.; George Perkins, Oxford Univ. and St. Thomas's Hosp.; Cyril Alban Raison, Birmingham Univ. and London Hosp.; Geoffrey Bower Richardson, St. Bart.'s Hosp.; Edward Stanley Smalpage, Sydney Univ. and London Hosp.; Henry James Drew Smythe, Bristol Univ. and London Hosp.; James Swan, Edinburgh Univ. and London Hosp.; Hugh Compson Trumble, Melbourne Univ. and London Hosp.; Cecil Pembrey Grey Wakeley, King's Coll. Hosp.; and John St. George Wilson, Liverpool Univ.

Licences in Dental Surgery were also conferred upon the following 38 candidates, who have passed the requisite examinations and have complied with the by-laws:—

J. H. Allwood, Liverpool Univ.; H. C. Apperly, Royal Dental; G. R. D. Bradfield, Guy's; L. H. Buchan, Bristol; E. Clark, Guy's; C. Cooke, London; J. M. Coplans, Edinburgh and St. George's; G. B. Cornwell, A. E. Croke, and J. W. Curtis, Royal Dental; F. W. Day and L. F. Fouraker, Guy's; C. H. Freeman, Royal Dental; F. D. Gratrix, Guy's; S. L. Hart, Univ. Coll.; A. L. Hyslop, P. Krige, and W. A. Krige, Guy's; E. H. Laurence, Univ. Coll.; F. H. E. Marston and T. A. Meldrum, Royal Dental; G. K. Moore, Guy's; H. S. H. Moore, Univ. Coll.; R. A. Moore, F. J. Myers, and F. D. Neal, Guy's; H. S. Paxton, Royal Dental; E. R. Pfaff, Bristol; H. K. Price, Guy's; A. Stafford, Sheffield; F. W. Stiven and G. M. Stuart, Guy's; M. H. G. Sturridge, Pennsylvania and Middlesex; C. S. Taylor, Durham and Royal Dental; W. A. Turner and H. C. Tweney, Guy's; C. P. M. Valette, Paris and Guy's; and J. W. E Warren, Guy's.

A report was read from the Dentists Bill Committee, and although the Council was of the opinion that the Bill was unsatisfactory in some respects, it had reason to believe that as a whole it was approved by most members of the dental profession, and for that reason did not propose to take steps to have amendments introduced.—The President reported that, in pursuance of the provisions of the Bradshaw Bequest, he had appointed Mr. H. J. Waring as Bradshaw lecturer for the coming year.—A letter was read from Mr. Robert Lindsay, Dental Secretary of the British Dental Association, who forwarded for the consideration of the College a copy of a scheme for the institution of a Diploma in Public Dentistry. This scheme was drawn up by the Dental Service Committee of the Association and approved by its Representative Board for circulation to all Universities of the United Kingdom and to all dental licensing bodies. The matter was referred to the College Committee for consideration.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of this Faculty held on March 7th the following were admitted (after examination) as Fellows of Faculty—viz., Dr. Samuel Saxon Barton (Liverpool), and Drs. Ronald Thomson Grant, Noah Morris, and James Russell (Glasgow).

FEDERATION OF MEDICAL AND ALLIED SOCIETIES.—The executive council of the Southampton Medical Parliamentary Committee has passed a unanimous resolution, which has been forwarded to us by the Federation of Medical and Allied Societies with a request for publication, to the effect that the council approves of the position adopted by the Federation in the formation of a body representative of the medical and allied professions.

THE Wellcome Historical Medical Museum will be closed for redecoration and cleaning from April 1st to 30th, inclusive.

TUBERCULOSIS SOCIETY OF GREAT BRITAIN AND IRELAND.—A meeting of this society will be held at Colindale Hospital, Hendon, to-day, Saturday, at 3 P.M., upon the invitation of Dr. Marcus Paterson, who will show members round the institution and give a short address. A clinical meeting of the society will be held in April and the honorary secretary, Mr. F. J. C. Blackmore, 39, Woodland-terrace, S.E. 7, will be glad to receive the names of members wishing to show cases. It is proposed to hold a post-graduate course in Paris at the latter end of May if a sufficient number of members join. Further information may be obtained from Dr. W. G. Dickenson, 1, Ridley Villas, Newcastle-on-Tyne.

RONTGEN SOCIETY.—A general meeting was held on Thursday, March 17th, at 8.15 P.M., in the Architecture Theatre, University College, Gower-street, London, W.C., when a paper on X Ray Dosage, with Special Reference to the Barium Platino-cyanide Pastille was read by Mr. E. A. Owen, D.Sc., and Miss Phyllis K. Bowes. A special meeting of the society will be held on Friday, May 6th, at 8 P.M., at the University of Manchester, when Professor W. L. Bragg will deliver a paper and Professor A. V. Hill will give a demonstration of some electro-physiological experiments. On the following day it is hoped to arrange visits to works of scientific interest in the district. The gallery of the Royal Photographic Society of Great Britain has been placed at the disposal of the society during June, when it is hoped that a collection of radiographs, illustrating the different practical applications of X rays, will be furnished by members of the society. The President of the society, Dr. Robert Knox, offers a special prize for work submitted by lay assistants engaged in the production of photographic results, working either as hospital assistants or as assistants in medical radiology. Members wishing to read papers or to show apparatus or lantern slides are requested to communicate with the honorary secretaries, Dr. R. W. A. Salmond, 51, Welbeck-street, London, W.1, or Dr. E. A. Owen, The National Physical Laboratory, Teddington, Middlesex.

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY. This institute, which was formed for the practical application of science to the human conditions of industry and commerce, has now been incorporated, and the first meeting of the council was held at 329, High Holborn, on March 3rd. The chair was taken by Mr. H. J. Welch of Messrs. Harrisons and Crosfield, Ltd., who referred to the influential support which had been given to the institute by many leading psychologists and physiologists, and by prominent men in industry and commerce. He referred to the three sections of the proposed work of the institute: Vocational guidance and selection, fatigue research, and movement study, the purpose of all of which, he said, was the elimination of human waste. The adaptation of scientific knowledge to the human factor in work would not only increase production at lower cost, but would also increase the happiness and contentment of mankind. He pointed out that the institute, was established to combine scientific research with practical work in commerce and industry. It was not established for profit, and all the fees received would be used to promote the objects of the institute. Dr. C. S. Myers, F.R.S., director of the Psychological Laboratory, Cambridge, who has been one of the moving spirits in the foundation of the institute, emphasised the necessity for careful research work and supported the chairman's statements as to the need for a practical application of the results of such work. The meeting was also addressed by Mr. Kenneth Lee, director of Tootal Broadhurst Lee Co., Ltd., Mr. Robert C. Witt, and others. An executive committee was appointed with power to manage the affairs and business of the institute generally, and to appoint subcommittees; a scientific committee has been appointed, which includes psychologists and physiologists from the Universities of Aberdeen, Birmingham, Cambridge, Edinburgh, Glasgow, Leeds, London, Manchester, and South Wales, and from various colleges and societies. It was announced that several firms were negotiating with the institute for the commencement of practical work in their factories, &c. The institute will depend for its income from three sources: (1) members' subscriptions; (2) donations; (3) fees for work done. A sum of £10,000 a year is required from the first two sources, and of this approximately £2500 a year for five years has already been promised. The subscription for membership of the institute for ordinary members is £1 per annum and for life members £25; members will be entitled to receive the periodical it is proposed to publish and any other literature issued from time to time. Full particulars and application forms for membership can be obtained from the secretary, Dr. G. H. Miles, at the offices, 329, High Holborn, W.C.1.

London Homœopathic Hospital.—The seventy-first annual general meeting of this hospital was held on March 15th, Lord Cheylesmore, the President, in the chair. The President announced that the Duke of York had consented to become a patron. Lord Donoughmore, in moving the adoption of the annual report, reviewed the financial situation and reported that in consideration of the increasing difficulties attendant on the efficient administration of the hospital, they had, in common with many of the larger voluntary hospitals, instituted early in the year the system of patients' contributions. He announced further that a sum of £6450 had been received to date in response to the special appeal for £7690 required for long deferred repairs and essential alterations. The balance of £1240 had still to be raised, and Lord Dysart had promised the last £500 of this amount if the balance were subscribed by July 31st, 1921. The ordinary expenditure for the past year was £8885 in excess of the ordinary income, which, together with the accumulated deficits since 1916, had brought the total deficit to £17,702. Increased annual subscriptions are greatly needed and should be sent to the Treasurer, London Homœopathic Hospital, Great Ormond-street, London, W.C.1.

Scottish Board of Health.—An urgent circular has been issued to local authorities by the Board on the need for economy. It is pointed out that in public health matters the present policy must be to restrict expenditure to immediate necessities, and developments which in normal times would be proper must be slowed down, all unnecessary items being eliminated. Existing premises should be improved rather than replaced by new accommodation, and rearrangement of present staff to meet requirements should be attempted. No fresh capital expenditure should be undertaken which can be postponed without material risk to the public health. In maternity and child welfare work expense should be reduced by encouraging voluntary service and by fixing suitable scales of payment for food and other supplies. In the case of sanatoriums approved, but not yet commenced, work should, as a rule, be postponed. Additional centres for the treatment of venereal diseases would be provided only where there was obvious deficiency. In terms of the Blind Persons Act local authorities should continue preparation of their schemes; these would be considered by the Board, but expenditure on new buildings would not be sanctioned easily. At present every inducement should be given to the continuance of voluntary effort.

Liverpool Royal Southern Hospital.—The annual meeting of this hospital was held on March 7th, Alderman E. Russell-Taylor, the Lord Mayor, in the chair. The annual report showed that during 1920 2157 in-patients were treated—a reduction of 183 on the previous year. The diminution was due to the return to the pre-war establishment of 218 beds as compared with an average of 230 beds in 1919. In the out-patient department the work had increased, there being 974 more new cases, involving 5656 additional attendances as compared with the previous year. The figures were: 1919, 70,593; and 1920, 76,249. A considerable amount of work was still being done for the Ministry of Pensions. During the year 97 ex-Service men were treated in the wards, and 5095 attendances were registered in the out-patient department. The V.D. department, the tuberculosis department, and the X ray and massage and exercise departments had all been increasingly used. The children's out-patient clinic, which worked in close association with the Invalid Children's Association, had become one of the best known clinics of the kind in the country. A trained woman—an official of the association—attended the clinic to instruct mothers concerning the dieting and general care of their babies, and other women engaged by the association visited the homes to continue this instruction. By these means the clinic had attained a high degree of efficiency in child welfare work. A special neurological department was established in July, 1920. The report[1] showed that the ordinary income was £2948 above that of the previous year—every source of income having shown an increase except the receipts in respect of ex-Service men. But, owing to the increased cost of commodities and the expenditure on long delayed works of cleaning and repair, the ordinary expenditure was £7030 above that of last year. The total ordinary income was £36,983, and the total ordinary expenditure was £24,361. A grant of £7500 was received from the Lord Mayor's Special Appeal Fund, but the amount from legacies was only £1807 as compared with £14,335 in 1919. There had been an increase in payments by, or in respect of, patients of £4652. Part of this very satisfactory improvement was due to the appointment of an almoner.

University of London.—At a meeting of the Senate held on March 16th the question of closing the Physiological Laboratory at South Kensington was again considered, and it was resolved to continue the laboratory until the end of the session 1922–23.

North-East London Post-Graduate College.—A special post-graduate course, adapted to the needs of the medical man in active practice, will be held at the Prince of Wales's General Hospital, N. 15, from Monday, April 25th, to Saturday, May 7th. It will include each day demonstrations of clinical and laboratory methods in the morning, and in the afternoon demonstration of groups of selected cases and either a clinical lecture or a clinical consultation. Demonstrations will also be given in associated special hospitals. A syllabus will be issued in due course, and will be sent on application to the Dean.

Hospital Conditions in Bristol.—At the annual meeting of the Bristol General Hospital on March 14th it was stated that the total number of in-patients had been 4031, a record number, and of out-patients 27,049. The income had been £26,000, an increase of 10 per cent. on the previous year, but the expenditure had advanced by 20 per cent. to a total of £45,000. To meet this very serious deficiency a system of collecting payments from patients, which was still under discussion with the committee of the Bristol Royal Infirmary, would probably be adopted. Similar financial difficulties were reported at the annual meetings of the Children's Hospital and the Eye Hospital. At the latter there was urgent need for a rebuilding scheme, but this appeared to be out of the question at the present juncture. Some allusion was made at the General Hospital meeting to the possibility of combination between the institutions, but it did not appear that any formal agreement was at present contemplated.

The late Dr. E. H. Buckell.—Ernest Hook Buckell, who died recently at his residence in Chichester, was in his sixty-ninth year, being the second son of the late Dr. Leonard Buckell of the same city. He came from a medical family and was educated at Epsom College, whence he proceeded to University College Hospital. Here he qualified, after a successful career as a student, in 1875, since which time he practised in Chichester and the district, succeeding his father as medical officer to the Bishop Otter Memorial College and the Chichester Poor-law Institution, as well as in an extensive private practice. For over 30 years he was honorary physician to the Chichester Infirmary (now the Royal West Sussex Hospital), and, resigning in 1919, was appointed honorary consulting physician. He founded the X ray department at that hospital, and its present state of efficiency is due to his work of some years ago. He was President of the Chichester and Worthing Branch of the British Medical Association in the same year. He will be greatly missed by the poor of the city and district, for his personal acts in relief of distress were numerous and extensive, and his devotion to duty great. He took a keen interest in public affairs and was for many years a member of the city council and also a justice of the peace for the city. To mourn their loss he leaves a widow and four daughters, one of whom married her father's successor in the practice, Dr. Walter Dick, and two sons, Dr. Ernest Buckell, who practises at Newport, Isle of Wight, and Dr. Aston Buckell, who is assistant bacteriologist at Durham University.

MEETINGS OF SECTIONS.

Monday, March 21st.

SECTION OF ODONTOLOGY: at 8 P.M.
Paper:
Mr. J. G. Turner: Dental Sepsis in Relation to Rheumatism and Allied Conditions.

Tuesday, March 22nd.

SECTION OF MEDICINE: at 5.30 P.M.
Papers:
Dr. Parkes Weber: Thrombosis of the Inferior Vena Cava and both Renal Veins.
Dr. Nathan Raw: The Treatment of Tuberculosis with Attenuated Tubercle Vaccines.

ROYAL SOCIETY OF ARTS, John-street, *Adelphi*, W.C.
MONDAY, March 21st.—8 P.M., Cantor Lecture:—Major G. W. C. Kaye: X Rays and their Industrial Applications. (III.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West *London* Hospital, Hammersmith, W.

MONDAY, March 21st.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Dr. Simson: Diseases of Women. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards. Mr. Baldwin: Visit to Surgical Wards.

TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 2 P.M., Dr. Burnford: Medical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2.30 P.M., Mr. Addison: Visit to Surgical Wards.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. D. Armour: Visit to Surgical Wards. Mr. Sinclair: Surgical Out-patients. Mr. Gibb: Eye Department.

THURSDAY.—2 P.M., Mr. B. Harman: Eye Department. Mr. MacDonald: Surgical Out-patients. Mr. Baldwin: Orthopædic Department. Mr. D. Armour: Operations.

FRIDAY.—10 A.M., Dr. Robinson: Gynæcological Operations and Visit to Wards. *Dr. McDougal:* Electrical Department. 2 P.M., Mr. T. Gray: Surgical Out-patients. Dr. Morton: X Ray Department. Dr. Pernet: Skin *Department.* 2.30 P.M., Dr. Pritchard: Visit to Medical Wards.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.
MONDAY, March 21st.—5.30 P.M., Post-Graduate Lecture:—Dr. F. W. Price: Heart Block.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.
TUESDAY, March 22nd.—4.30 P.M., Lecture:—Dr. D. E. Core: *Some Principles in the Treatment of Neurasthenia.*

Appointments.

GOODWIN, A., M.D., F.R.C.S., has been appointed Pathologist to *the Chelsea Hospital for Women.*

HIRSCH, C. T. W., late Captain, R.A.M.C., M.R.C.S., L.R.C.P., Anæsthetist to the Hospital for Epilepsy and Paralysis, Maida Vale.

JOHNSTON, W. H., M.D., F.R.C.S. Edin., Medical Superintendent to Highbury, Uffculme, and Sorrento Hospitals, Birmingham.

RICHARDS, H. A., B.Ch. Cantab., Junior Anæsthetist and Assistant *Instructor in Anæsthetics to King's College Hospital.*

Certifying Surgeons under the Factory and Workshop Acts: PIRRIE, R. R., M.D. Durh. (Eastbourne); BANKES-PRICE, H., M.R.C.S., L.R.C.P. Lond. (Chipping Campden); HOGAN, W. L., M.B., B.Ch. Dub. (Warminster); COULSON, T. E., M.D., Ch.B. Edin. (Wincanton); WILLIAMS, W. H., M.R.C.S., L.R.C.P. Lond. (Monmouth).

Vacancies.

For further information refer to the advertisement columns.

Aylesbury, Royal Bucks Hospital.—H.S. £200.
Birmingham General Hospital.—Asst. Visit. Anæsth. £50.
Birmingham, Rubery Hill and Hollymoor Mental Hospital.—Jun. Asst. M.O. £400.
Birmingham, St. Chad's Hospital.—Res. M.O. £100.
Birmingham, Queen's Hospital.—H.P.'s, H.S.'s, Obstet. and Ophth. H.S., and Cas. H.S. £90 each.
Blackburn and East Lancashire Royal Infirmary.—Third H.S. £250.
Central London Ophthalmic Hospital, Judd-street, W.C.—Path. £75
Charing Cross Hospital, Agar-street, W.C.—Surg. Registrar. £150.
Chelsea Hospital for Women, Arthur-street, Chelsea, S.W.—H.S. £120.
City of London Hospital for Diseases of the Chest, Victoria Park, E. H.P. £100.
Darenth Training Colony.—Jun. Asst. M.O. £422.
Dewsbury and District General Infirmary.—H.S. £250.
Dewsbury County Borough.—Asst. Sch. M.O. and Asst. M.O.H. £500.
Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.
Durham County Education Committee.—Asst. Oculist. £600.
Ealing Borough.—Asst. M.O.H. £500.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsth. £50. Also Ophth. S.
Glamorgan County Asylum, Bridgend.—Jun. Asst. M.O. £415.
Great Northern Central Hospital, Holloway, London, N.—P. Also Anæsth. £10 10s.
Greenwich, "Dreadnought" Hospital.—H.S. £150.
Guildford, Royal Surrey County Hospital.—H.S. £150.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Registrar. £100.
Hospital for Sick Children, Great Ormond-street, London, W.C.—Asst. Cas. M.O., H.S., and H.P. £50 each.
Hospital for Women, Soho-square, W.—Clin. Assts. to Out-patients.
Huddersfield Royal Infirmary.—Sen. H.S. £250. Two Jun. H.S.'s £150.
Leicester Royal Infirmary.—H.P. £200.
Lewisham, St. John's Hospital.—H.S. £150.
Lincoln County Hospital.—Jun. H.S.—£150.
London Homœopathic Hospital, Great Ormond-street and Queen square, Bloomsbury, W.C.—Two Res. M.O.'s. £100.
Manchester, Ancoats Hospital, Mill-street.—Med. Registrar and Surg. Registrar. £100 each. Res. Surg. O. £250. Res. H.P. £200. Anæsth. 10s. 6d. per attendance.
Ministry of Pensions Hospital, Cannock Chase, Hednesford, Staffs.—S. £600.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—H.P. £150. Asst. P.
Newcastle-upon-Tyne City Mental Hospital, Gosforth.—Jun. Asst. M.O. £350.
Newport, Mon., Royal Gwent Hospital.—H.S. £200.
Norfolk Education Committee.—Asst. Sch. M.O. £500.
Northampton General Hospital.—H.S. £200.
Nottingham.—Asst. to City Pathologist. £500.
Nottingham City Asylum.—Sec. Asst. M.O. £400.
Oldham Royal Infirmary.—H.S. £200.
Paisley Parochial Hospital Lunatic Wards and Poorhouse, Craw-road.—Res. P. £300.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Cas. H.S., Asst. Cas. O., and H.P.'s. £100.
Rotherham Hospital.—Jun. H.S. £150.
Royal London Ophthalmic Hospital, City-road, E.C.—Refraction Asst. £100.
St. Bartholomew's Hospital Medical School.—Chair of Anatomy. £900.
Salford Royal Hospital.—H.S.'s, and Cas. H.S. £150.
Salop County Council, Medical Inspection of School Children, Maternity, and Child Welfare.—Asst. M.O. £517 10s.
Samoan Medical Service.—Three Jun. M.O.'s. £600.
Sheffield Royal Hospital.—H.S. and Asst. Cas. O. £150.
Sheffield Royal Infirmary.—H.S. £150. Ophth. H.S. £150.
Southampton Free Eye Hospital.—Asst. Hon. Ophth. Surg.
South Shields, Ingham Infirmary and South Shields and Westoe Dispensary.—Jun. H.S. £175.
Swansea County Borough.—Asst. M.O. £500.
Tiverton Hospital.—H.S. £100.
Wakefield, Clayton Hospital.—Sen. H.S. and Jun. H.S. £250 and £200.
Western Dispensary, 38, Rochester-row, Westminster, S.W.—Res. M.O. 100 guineas.

THE Chief Inspector of Factories, Home Office, S.W., of vacancies for Certifying Surgeons under the F Workshop Acts at Oldham and at Manchester.

Births, Marriages, and Deaths.

BIRTHS.

DEBENHAM.—On March 6th, at The Crescent, Scarborough, the wife of L. S. Debenham, M.B., B.S., B.Sc., of a son.

McCALL.—On March 10th, at Malton, Yorkshire, the wife of H. Dundas McCall, M.R.C.S., L.R.C.P., of a son.

WHITEHOUSE.—On March 13th, at Wickham-road, St. John's, S.E., the wife of W. H. Whitehouse, M.D., of a son.

MARRIAGES.

GWYN-DAVIES—GREENWOOD.—On the 28th February, at Holy Trinity Church, Folkestone, W. L. Gwyn-Davies (late Captain, R.A.M.C.), to Elvira, only daughter of W. Greenwood, Esq., Barrister-at-Law, of Folkestone.

WILLIAMS—COLLEY.—On March 15th, at St. Mary the Virgin, Speldhurst, Kent, Gwilym Ambrose Williams, B.A., M.R.C.S., L.R.C.P., to Dorothy, younger daughter of the late Robert Colley, of Paddington, and Mrs. Colley, Speldhurst.

YEO—DEWAR.—On March 12th, at St. John's Presbyterian Church, Kensington, Kenneth John Yeo, M.A., M.R.C.S., L.R.C.P., to Sheila, younger daughter of the late David Douglas Dewar and of Mrs. Dewar, Bourne End Cottage, Boxmoor, Herts.

DEATHS.

BRADLY.—On March 15th, at Crowborough, Norman Bradly, M.D., aged 36.

HOLLIS.—On March 12th, at Redenhall, Harleston, Norfolk, Harry Hollis, M.D., late of Wellingborough, aged 52.

STOREY.—On March 10th, at Southdene, Dunstable, James Alexander Storey, L.R.C.S.I. and L.R.C.P.E., late of The Lawn, Dunstable, aged 72.

SYMONS.—On March 11th, at Trevalga, Lansdown-parade, Cheltenham, John Trehane May Symons, Brigade Surgeon, M.D., in his 88th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. R. E. Apperly, Lond.

B.—Dr. A. M. Barford, Chichester; Dr. L. Boudreau, Bordeaux; Mr. G. N. Biggs, Lond.; Sir J. Bland-Sutton, Lond.; Dr. L. S. Burrell, Lond.; Board of Control, Lond.; Mr. H. W. Bayly, Lond.

Notes, Short Comments, and Answers to Correspondents.

THE IDEAL ELEMENT IN MEDICINE,[1] ILLUSTRATED BY THE LIFE OF JOHN HUNTER.

BY H. H. BASHFORD, M.D., B.S.LOND.

I MUST first of all thank you for the unexpected honour that you have done me in asking me to read this annual paper; and, at the same time, I must ask you to forgive me for not bringing with me anything at all original. But we are here primarily, I suppose, to do homage, to commemorate rather than to create, and there is no figure, perhaps, that has more worthily embodied what I have ventured to call the ideal element in medicine than the Scottish farm-boy in whose name this ancient society meets and has its being. That must be my excuse for embarking on what is obviously a dangerous topic. For most of us here, I suppose, are Anglo-Saxons, and it has been shrewdly said of the Anglo-Saxon that his genius has consisted in perceiving just how much of an ideal is comfortably workable. In the pursuit of abstract truth or social liberty he has generally been content to stand aside and let the more ardent and easily moved nations make the sacrifices of the pioneer; and the deduction from that is that, in any body of Englishmen, there will always probably be a considerable proportion that looks upon ideals and idealists with a rather grave suspicion.

It is also dangerous for another reason, to which I am a little diffident in referring. But some of you may recall that in a recent play a somewhat cruel test was propounded. Have you noticed, it was asked, how young the policemen look? Well, gentlemen, that is an observation that most of us here, I am afraid, must have made; and it was stated by the playwright—a member of our profession—to be an infallible sign of the presence of middle age; and middle age, as we have all been told, is the deathbed of idealism. But we have not always been middle aged, and there are crowding in behind us, and perhaps even looking to us for guidance, those younger men and women who are desirous of dedicating their lives to the Science and Art of Medicine.

The Doctor as Artist.

I am rather sorry that just at present we hear so little of Medicine as an art, since it is chiefly, I think, as we regard it from this standpoint that its ideal element becomes manifest. For, though Art has never yet, perhaps, been successfully defined, it is in any case a giving-out, a yielding-up, an expression—the concrete acknowledgment, in some shape or other, of the god-like privilege of consciousness. The true artist, whether he would or not, is thus always an altruist; and, though he is ever in pursuit of an ideal that he may never attain, he is yet the happiest man alive, whether renowned or obscure; and it is pleasant to think, and surely it is true, that, in a large proportion of cases, it is this embryo artist in them that is compelling our successors towards the arms of medicine.

About that there are probably many of you here far better qualified to speak than I. But the fact remains that somehow and somewhen Medicine has taken this high step; that it has assumed the distinction, and therefore the obligations, conferred by the banner of Art; and that it has thereby proclaimed in itself an ideal element lacking which it must surely die. That is why we may assume perhaps—even the most disillusioned of us—that it is still recruiting the young idealist; and why it may be not uninteresting, just for two or three minutes, to reflect upon the condition in which he will find it. In the contemporary life of our community to-day, in the minds and affections of our fellow men, in what sort of position, in what kind of regard will he find this great art of ours and its practitioners?

The World when Hunter was Born.

Well, there is no better way, perhaps, of answering such a question than to use the method of comparison; and it is one of the advantages of an occasion like this, when we meet to commemorate a great man dead, that we find in his person a past milestone naturally provided, as it were, for the purpose. Let us glance, therefore, for a brief moment at the world into which Hunter was born, and the sort of part in it then played by the physician and surgeon. He was, as you know, born in 1728, 21 years after the union between Scotland and England, but only 13 since a Scottish army had invaded England as far south as Preston. George II. was on the throne, and it is interesting at the present moment to recall that we were then united with France and Prussia in a triple defensive alliance. Both in India, indeed, and North America, the territories of France were more extensive than our own. The Cape of Good Hope was in the hands of the Dutch. Spain was predominant in South America, and only one ship a year was officially allowed to trade between this country and her pacific ports. Isaac Newton had been dead a year; Defoe was still living; Johnson and Sterne were in their teens, and Henry Fielding had just come of age; John Wesley was 25; Voltaire was in England as an honoured guest; Pope was publishing his Dunciad; and it was the year in which Swift lost his Stella.

---

[1] Being the annual oration of the Hunterian Society delivered on Feb. 16th, 1921.

Hunter was born, as you will also recollect, about seven miles from Glasgow, then a little country town about the size of Banbury, and six days' journey from London in a fast chaise. By more usual methods the journey took nearly a fortnight, but a daily horse-post had just been instituted, the arrival of the postman from Edinburgh, at six every morning, being signalised by the firing of a gun. The chief industry of the town was weaving, and it had already made a small reputation for the production of blue and white check handkerchiefs, a novelty not long introduced from Germany. Many of these linen goods were shipped abroad, chiefly to the North American colonies, and the Glasgow merchants were making fortunes out of the tobacco that their ships brought back. They owned between them about a score of these ships; the first home-made one was already ten years old; and their total tonnage amounted to about one-ninth of that of the *Olympic* or *Aquitania*. There were also, I believe, 300 yards of pavement, upon which these merchants would take the sun, where doubtless the little Hunter looked with admiring eyes upon their cocked hats and scarlet coats.

But Glasgow was not typical of a country where payment in kind was still almost universal, although the paper money of the new Bank of Scotland was beginning to supply a crying need, and the union with England had already begun to react in an increased prosperity north of the border. Both countries still remained, however, predominantly agricultural, although the first stirrings of the coming industrial era were now beginning to be felt. Liverpool, for example, had just completed its first dock, and there were already 50 streets in Birmingham. But the day of the factory had scarcely dawned; industry, such as it was, remained chiefly domestic; and these islands slept, perhaps happily unconscious of all that lay hidden in their coal and iron. Roads were scarce, and a Scottish gentleman desirous of travelling from Edinburgh to London would have found no turnpike beneath the wheels of his carriage until he arrived at Grantham. It would have been highly necessary for him to be well armed, and the cost of the journey, had he desired a reasonable comfort, would have been equivalent in modern money to that of a first-class ticket to Australia to-day.

Social Conditions and Conventional Beliefs.

Throughout the journey he would have been passing through a country of which the majority of the people could neither read nor write;-wherein even the humanest could watch with equanimity a lad swinging on the scaffold for the theft of a shilling; and at his destination, if he had chanced to refresh himself at Lloyd's coffee house in Abchurch-lane, he would have met godly and generous merchants who were making their fortunes out of the African slave trade. As a Lowland Scot he would probably have been brought up in a lively apprehension of hell-fire, and the memory would have been fresh in his mind of the sentence of death passed only the year before upon a woman in Sutherland for having ridden upon the back of her daughter, who had been changed into a pony and shod by the devil. Had he postponed his journey till Hunter was six years old he might have been reading in his carriage the latest treatise on law by Professor Forbes, of Glasgow, in which he distinguished black witches, who did harm, from white witches, who performed cures, in both cases owing to their intimacy with the powers of darkness. Both he and the professor would probably have believed themselves, as members of the human race, to have been the products of a separate and special act of creation, and to have been the inhabitants of a world—according to the accepted notation of Bishop Ussher of Armagh—5732 years old.

I say probably because, like all ages, this early eighteenth century was transitional; and a picture confined to the little minority of the educated, travelled, and governing classes—and especially, perhaps, south of the border—would reveal a somewhat different mental environment. Tired and contemptuous of the theological quarrels of a couple of generations earlier, the prevailing habit of thought in these smaller circles was sceptical, tolerant, and lazily amenable to the newer speculations that had arisen from the researches of Copernicus, Kepler, and Newton. Largely recruited from these classes, the Anglican clergy—or at any rate their beneficed ranks—offered no very heart-felt opposition, and, indeed, to a great extent shared both in their relatives' materialism and the moral slackness that had resulted from it. This was the little but powerful England, of which Sir Robert Walpole was a representative figure. It was the England that was to shine through the letters of Chesterfield, then our ambassador at The Hague; it was the England of Squire Western, soon to be pictured for us in immortal colours by Fielding; and it was the England that provoked, just as it was to temper, the crusades of John Wesley.

But it was not from this small and privileged society that the majority of doctors was then recruited, and that is why, perhaps, the weeds of mediævalism still clung so perceptibly about their practice. Finally divorced from the ranks of the clergy and the jealous control of the Church, their recognition as members of an independent, authoritative, and learned profession was still far from complete. That was, perhaps, even more the case in these islands than in many parts of the continent, and especially, at the moment, in Holland, Italy, and France.

Great Men of the Time.

Here and there, no doubt, in every country particular men were standing out, men whose gifts had already procured for them a wide academic and social influence. Much the best known of these, in the popular sense, was, of course, the famous Boerhaave, then in the zenith of his activities at the University of Leyden, and perhaps the most sought-after physician of his own age or any other. There was probably well marked in him the quality that we have learned to describe in these days as "bluff." But he seems to have been a kindly and painstaking teacher, and possibly, indeed, the founder of modern clinical instruction. He it was to whom, without question, there is said to have been delivered a letter from the Emperor of China, merely bearing an address to the most famous physician in Europe; and he is also reported to have kept Peter the Great waiting a whole night for a consultation. Other great figures in the year of Hunter's birth were the surgeon Georges Mareschal, of Paris, with his record of eight lithotomies successfully performed in half an hour, Hoffmann at Halle, and Stahl at Berlin. But for the most part, and in every country, the village ancient and the strolling cure-monger still plied a trade often scarcely distinguishable from that of the more official medical practitioner.

Thus in Hunter's own country, at the time of his birth, all that was required before qualification—before the conferring, that is to say, of the title of surgeon apothecary—was a three years' apprenticeship to some surgeon apothecary already in practice, who was himself, in too many cases, a deeply ignorant person. The candidate had then to appear before the College of Barbers and Surgeons—the barbers, by the way, had recently dropped out—when he would be required to dissect a part, write a thesis, and make up a prescription. With regard to drugs, the properties of quinine and mercury were by then, of course, pretty well known; but the average prescription of 1728 affords plenty of evidence of the enormous ascendancy tradition still held over accurate observation.

A Popular Physician.

Perhaps the most popular physician, for example, then in Scotland was a Dr. Clark of Edinburgh, a man who was able, like his more famous contemporary, Dr. Mead of London, to command what was still, as a regular fee, the comparatively rare sum of a guinea. "The person suffering from pleurisy," he advised, "must take a ball of horse-dung, well dried, beat it into powder, drink it, and he will be cured." On another occasion he prescribed for a child "the juice of 20 wood-lice squeezed through a muslin bag, to be drunk twice a day." Universally the excrement of domestic animals and the juice of snails and wood-lice were advocated. A popular cure for whooping-cough was the application of five leeches behind the sufferer's ear; and whitlows were said to disappear after the affected finger had been thrust for half an hour into the ear of a cat. Tremendous stress, too, seems to have been laid upon the number of ingredients employed in a medicine, and even the great Sydenham, who a generation earlier had stood like a rock for sanity and simplicity, had employed no less than 18 herbs in the composition of a single ointment. Somewhere hidden up in all this there was doubtless an element of rough empirical wisdom. Perhaps more evidently there still lingered traces of the occult lore of the Middle Ages. But it is to be feared that the remainder was chiefly the stock-in-trade of a more or less unconscious charlatanism.

So Many Men, So Many Systems.

That is far from denying, of course, the profound and tonic influence of a mind like Sydenham's, or forgetting the results already achieved by exact and unbiassed experiment. In what may be called, perhaps, the higher circles of the very loosely knit medical brotherhood, the researches of Harvey, for instance, on the circulation had long been known and accepted. The thermometer had been discovered and tentatively used, here and there, as a clinical instrument; and the primitive microscope had revealed, 50 years before, the presence of red corpuscles in the blood. The French invention of the tourniquet, as distinct from the ligature, was of about the same age; and inoculation against smallpox had just been introduced into England by Lady Mary Wortley Montagu—that she-meteor, as Horace Walpole described her—although it was being strongly opposed by the clergy as an interference with the divine prerogative.

With but few exceptions, however, the mind of contemporary Medicine was still largely clouded by the mediæval legacy of formulating in advance some all-embracing hypothesis with which facts and treatment had to be made to square. Thus Professor Stahl, a chemist of renown, and one of Boerhaave's most brilliant pupils, refused to prescribe cinchona bark, because he held that the soul governed the organism by means of the circulation, and that fever was an expression of the soul's efforts to preserve the body from death. His contemporary, Hoffmann, on the other hand—the well-known Hoffmann of Hoffmann's anodyne—seems to have governed his treatment according to a theory that ether was the perceptive soul; that it resided in the medulla; and that fever was a spasm of the blood-vessels, with its origin in the spinal cord. So many men, so many systems, it seems to have been an age of systems, sired, as a rule, by some new fact, misinterpreted or over-exalted, and still mothered by a decaying, if not half-dead, theology.

The Era of Exact Observation.

Preserving our conception, however, of Medicine as an art, that is after all merely a question of method. Largely owing to the influence of Hunter himself, it has been succeeded by an era of exact observation, of the patient collection of innumerable facts, of a general dispersal of inquiry, of the careful tracking down of individual disabilities to their individual causes, and the consequent influx into the studios of Medicine of a hundred different kinds of specialist. Presently this method will change, and nothing is more probable than that some Hunterian orator, 200 years hence, will be marvelling at our blindness to the great synthesis already quivering to be born; at our assiduity in trying to stop up a hundred thousand separate leaks, when some basic principle was staring us in the face, whereby the whole vessel might be made water-tight. On the other hand, he will be unable to deny, I think, the enormous stride into general influence, into the recognition of the community at large, that the art of Medicine has made in these last two centuries.

(To be concluded.)

COLONIAL HEALTH REPORTS.

British Solomon Islands.—From March to May, 1919, there was a widespread epidemic of influenza, with characteristics not previously experienced in the Protectorate, but similar in kind to the pandemic disease found everywhere else. At Tulagi, out of 225 cases there were 8 deaths, but it is impossible to estimate the numbers who died on the other islands. The complications and sequelæ noticed after influenza were for the most part, so far as could be observed, bronchitis, broncho-pneumonia, and pleurisy. Recruiting was stopped for two months, and all indentured labourers were inoculated with vaccine supplied from Melbourne. The natives at large were without treatment except those in the vicinity of Government or Mission stations. Admissions to Tulagi Hospital numbered 520, of whom 35 were Europeans and 485 natives. The number of deaths was 30. 4436 out-patients were treated. Malaria in its various manifestations and dysentery affect Europeans and natives equally, and during 1919, a year of exceptional sickness, few escaped. The absence of any organised native administration and lack of transport make it impossible to obtain accurate returns of the population, but district officers have devoted much time and attention to the matter, and on some islands careful records of births and deaths have been made. They all show a diminishing birth-rate, the most serious loss being on San Cristoval with 401 deaths and 241 births. Depopulation is attributed to various causes, amongst which must be placed the epidemics of dysentery and influenza. Amongst non-natives 7 deaths were recorded during the year and amongst indentured natives 104 deaths, giving a death-rate of 19 per 1000.

Ashanti.—Mr. Arthur J. Philbrick, as acting Chief Commissioner, is responsible for a report recently presented to Parliament dealing with the affairs of Ashanti for the year 1919. He states that the population, which at the Census taken in 1911 was 287,814, has undoubtedly increased considerably since that year in spite of the large number of deaths from influenza in 1918. The population of Coomassie, the capital, is increasing, and may be estimated approximately at 26,000. The provincial medical officer reports that the general health of the European and native population continued good throughout 1919. There was no epidemic, with the exception of a mild form of influenza in November. The most prevalent diseases were those of the digestive system, bronchial affections, ulcers, and malaria. Venereal diseases were most pronounced amongst the soldiers in Coomassie. The native population suffer chiefly from gonorrhœa, &c., but the establishment of a venereal clinic in connexion with the native hospital cannot fail to give satisfactory results. Two cases of smallpox were treated in the Contagious Diseases Hospital. Leprosy is stated to be common. The natives are not alarmed at it, and mingle freely with lepers, for whom it is intended to provide an agricultural settlement. The total rainfall during 1919 was 37·08 inches at Coomassie (the lowest for ten years), 41·30 at Sunyani, 79·58 at Kintampo, and 45·28 at Obuasi. The number of European in-patients treated in hospitals during the year was 100, and that of native in-patients was 1511; the European out-patients numbered 34, and the native out-patients 11,706.

Gambia.—No complete vital statistics for the Colony or Protectorate are available, but in Bathurst, the chief town, the death-rate in 1919 was 35·28 per 1000 of population. Malaria has decreased considerably, but venereal disease, tuberculosis, and amœbic dysentery are stated to be on the increase. The tsetse fly abounds in many parts of the territory. The natives appear to have become immune to a great extent. Four cases of sleeping sickness, with 2 deaths, were reported in Bathurst in 1919. The area of the Gambia is 4132 square miles—rather larger than Cornwall and Devon together. The population is estimated at about 240,000, of whom 8000 live in the capital—Bathurst—at the mouth of the river. The inhabitants belong to a number of tribes with widely differing racial characteristics, and speaking different languages. The European population is less than 200, composed of officials, traders, and a few missionaries. The climate is less unpleasant than that of the other West African colonies, though it does not follow that it is more healthy. The mean temperature is 77°, with a mean daily range of 15°. Rain falls between June and October. For some cause which has not hitherto been explained the average annual fall is diminishing.

A TUBERCULOSIS RECORD CARD.

DURING discussion on the report recently drawn up by tuberculosis officers in the London area, the necessity became apparent for clinical records to be kept in a uniform manner in order to be interchangeable as well as comparable. In the course of the year many tuberculous patients pass from one district to another and without some simple and convenient record much time is lost and previous investigation wasted. The main facts to be recorded being agreed upon a card was devised on which the information about a case was divided into linear groups consolidating the records under the heads of: (1) Diagnosis, (2) Grounds for Diagnosis, (3) Important Dates, (4) Personal History, (5) Family History, (6) Social Conditions, and (7) Treatment. Provision is thus made for the compilation of statistics in each division, the figures for the year being readily calculable. The reverse of the card provides for a history of the treatment and its results with space for four sets of chest diagrams to be filled in at stated intervals: (1) condition when case is first seen; (2) condition on discharge from sanatorium; (3) after 12 months; (4) after 2 years. At the bottom of the card is a key to the uniform method of recording physical signs in the chest. Dr. H. E. Ellis informs us that Carter-Parratt, Ltd. (2, Farringdon-avenue, Shoe-lane, London, E.C. 4), have had the cards printed for their patent "Bizada" overlapping card system, whereby the names can be seen at a glance, and either side of the card consulted. The system of record marks an advance on the present practice, and it is hoped that the London County Council may recommend its adoption as a first step towards the unification of tuberculosis statistics.

Mackenzie Davidson Memorial Lecture

ON THE

IMPORTANCE OF THE INFINITELY LITTLE.

Delivered before the Section of Electro-therapeutics of the Royal Society of Medicine on March 18th, 1921,

BY W. D. HALLIBURTON, M.D. LOND., F.R.S.,
PROFESSOR OF PHYSIOLOGY IN KING'S COLLEGE, LONDON.

IN 1798 there died in Bologna one who was born and lived there. His name, which has reverberated down the ages, was Aloysius Galvani. Destined for the Church of Rome, but later expelled from that body, he happily turned to science, and became professor of anatomy and physiology at the University of his native city in 1762. The story of his well-known discovery of what was later called galvanism is well known and does not need recapitulation here. Helmholtz, writing nearly a hundred years later in an appreciation of Galvani's pioneer work, said:—

> When Galvani touched the muscles of a frog with different metals and observed their contraction, who could have dreamt that all Europe would be traversed with wires flashing intelligence from Madrid to St. Petersburg with the speed of lightning? In the hands of Galvani, and at first even in Volta's, electrical currents were phenomena capable of exciting only the feeblest force, and could not be detected except by the most delicate apparatus. Had they been neglected on the ground that the investigation of them promised no immediate results, we should now be ignorant of the most important and most interesting of the forces of nature.

Had Helmholtz been alive to-day, how greatly might he have expanded this theme; for even he did not foresee the possibilities of electricity and its ramification into every branch of our daily life, including its applications for the detection and alleviation of many of our ills. Animal electricity in its medical aspect is, it is true, as old as galvanism itself. In its early days thinkers imagined the secret of life had been found, and attempts were made to convert dead into living bodies by its means. It soon lent itself to the worst forms of charlatanism and quackery. But as knowledge progressed and ignorance was dispelled it found its proper sphere, and the importance of the sphere is evidenced by the existence in our Royal Society of Medicine of a section devoted to electro-therapeutics.

To trace even in outline the various steps which have led to the present proud position in which this branch of science stands to-day would be a task beyond my powers and beyond your powers of endurance, but I may take as my text to illustrate one feature in the advance, if not its mainspring, a reminiscence of my own.

Attention to Minute Detail.

In 1888 I attended at Bath a meeting of the British Association, and as it was almost the first I had been to I listened to the presidential and other addresses with great attention. The president that year was the great engineer, the late Sir Frederick Bramwell, and well do I remember how he started his address. He began by alluding to a speech he had heard from the late Lord Iddesleigh, who charmed an audience for a whole evening by speaking on the very important subject, "Nothing." Sir Frederick Bramwell said he would not try to copy this feat, but would do his best to speak on "Next to Nothing." By this neat phrase he meant those little things which are of supreme importance. He gave numerous examples from his own subject to show how it was that attention to details had converted crude machinery into effective and useful instruments, whether they were guns or bridges, engines or ships. Among other subjects he took to illustrate his theme I remember he singled out the telephone as a triumph of science which the "next to nothings" had done so much to perfect. At that time he was naturally not aware of how in later years red-tapeism, and the like, would have taken upon itself to neutralise some of the excellent qualities that science had bestowed upon it. At the conclusion he ventured to prophesy that it would not be long before men were able to fly.

But gifted as Sir Frederick Bramwell was with the prophetic instinct he did not at that time, now 33 years ago, foretell the discovery of those vibrations which it is now customary to term X rays, nor of those other kinds of radiant energy which the name of radium calls up. Still less could he have predicted the value of these discoveries to medicine and to surgery, and least of all would he have pictured even in imagination the coming of a man who so fully illustrated the importance of attention to details, to the "next to nothings," a personality whose name we are met together to commemorate this evening. Sir James Mackenzie Davidson, whose sterling and genial character we all remember with affection, was first and foremost one who never spared trouble; he was one whose numerous inventions, the result of his painstaking attention to apparently small and trivial things, succeeded in making the bare bones of his subject live, just as his skiagrams represented them in life-like perspective.

The Physiologist in Medicine.

I wish that your section could have selected someone more capable than myself of dealing with this subject from the technical point of view. But you could not have chosen one who has a greater admiration for the genius and ability of our lamented friend. Your choice has fallen on a physiologist whose labours have been more directed into chemical than physical channels, and I regard it not so much as a compliment to myself as an honour to our band of quiet workers who are seeking out the ways of Nature by the way of experiment, and are doing their best to give to the art of medicine the sound basis of scientific knowledge. For too long the workers in the laboratory and those by the bedside have been groping out their own salvation in separate ways. Your request that a physiologist should address you to-night is evidence that the entente between us which is now happily growing needs still further strengthening. I feel that it does us all good to get at times out of our own special ruts.

Before coming to what, after all, is my main subject, there is one general consideration which I should like to place before you. The crowded condition of the medical curriculum in which the poor unfortunate student is presented with an ever-growing number of subjects for study while the length of the day still remains at the usual standard of 24 hours, is producing just now one of those attempts which recur periodically to revise his scheme of study. We are told that there is no need for him to learn his anatomy so thoroughly, that his organic chemistry must be reduced to a minimum; and, last and worst, his physiology course must be drastically shortened, and this in spite of the fact that all these subjects are growing fast, and that medical men are seeing more and more the truth that physiology is the corner stone around which the superstructure of medical science is built. Although physiology still figures on paper as quantitatively large, the restriction suggested is in the kind of physiology to be taught, and the word applied physiology designates that what is wanted for the student is physiology in its direct bearing on medical practice. The frog, which has served for so long as the object lesson of so many physiological precepts, is to be deposed from its high position, and, so far as is possible, experiments on man himself are to be substituted.

Value to Mankind of Purely Scientific Effort.

In speaking of Galvani's work, I have already given one example of how a subject of purely scientific interest, studied with no ulterior or utilitarian motive, was found to be of inestimable value to mankind. Such instances could be multiplied indefinitely. How would Lister's work have been possible without the preliminary academic labours of the chemist Pasteur? W
Miescher set out to investigate the chemistry of
roe of the salmon, did he think that it would be on
investigation that our knowledge of the pathol
gout would be founded? When Bayliss applied

to study colloids he could not have dreamed that a powerful weapon against wound shock would be discovered in that by-path. But I need not weary you with other instances. When a scientific man studies nature for the sake of pure knowledge, who can say to what practical use his followers may adapt it? In deciding in my own mind whether I approve or disapprove of these attempts to reform or revolutionise medical training, I am torn by conflicting emotions. On the one hand, I sympathise deeply with the student, and realise the impossibility of getting a quart into a pint jug; on the other hand, there is my love of pure science, and the conviction that any and every truth must ultimately bear practical fruit. I am not conservative by nature, and welcome every true reform, and I have little sympathy with the legendary professor at one of our ancient seats of learning, who, at the end of a life devoted to laborious research, thanked God he had never done anything that would be of the slightest use to anyone. One has in such an impasse to face facts and exercise one's common sense. A thorough grounding in general physiological knowledge must remain a sine qua non, but in the details of its many ramifications one must make a judicious selection, and the choice must naturally first fall on those parts of the subject in which the practical outcome is already realised rather than on those the application of which is still to seek. From the point of view of those in this section and of those who aspire to join its ranks later, one trusts that the electrical phenomena which are so easily demonstrated in all essentials on the muscles and nerves of frogs will not fall under the ban of those who are trying to limit the excursions of the student into the scientific aspects of the subject.

The occasion may not be inopportune to say a few words on some of the modern problems of physiology and tell you briefly the progress we have made and are making at the present time. To attack all these questions in the space of a single address would be impossible. Again, one has to make a selection, and I intend to limit myself to three. I think it will be found that in these three cases the importance of the "next to nothing" principle will be abundantly illustrated. This is the day of great things, because we are realising the importance of the infinitely little.

Hormones.

The invention of the word hormone dates from the discovery made by Bayliss and Starling of the chemical messenger which is elaborated in the intestine under the influence of the gastric acid, and which, after absorption, stimulates the pancreas to pour out its juice at the time when it is wanted to carry on to completion the digestive work begun in the mouth and stomach. Previous to this time we were imbued with the teaching that the harmonising or, to use Sherrington's phrase, the integration of the bodily functions is due to the activity of that ruling system of the body known as the "nervous system." The nervous system is not displaced from its high estate, but for the first time in the history of our science we realised to the full the valuable help rendered to the telegraphic service of the body by humbler but none the less useful ministers to our comfort which Starling aptly compared to the postmen.

Although the actual word hormone was not coined until secretin was discovered by Bayliss and Starling, the importance of chemical agents had been really recognised earlier, and more especially in relation to that group of formerly mysterious organs known then as the ductless glands, but now generally dubbed the endocrine organs; they are so called because they form an internal secretion—that is, a secretion which leaves by no specific duct, but by the blood or lymph that streams from the organ in question. It was no wonder that ignorance prevailed for so long as to their function, seeing that the new chemical principle each forms is masked by the protein-rich fluid which it enters. But now, thanks to the overcoming of this and other difficulties, we know a great deal about the thyroid, the adrenal body, the pituitary gland, the islets of Langerhans, the corpus luteum, and others.

Many details have still to be worked out, and some of our ductless glands are territories almost as unknown as Central Africa was in our youthful days. The chemical messengers are all grouped together under the general name hormone, a term which immediately "caught on." Attempts have been made to distinguish classes among the chemical messengers to indicate that some stimulate, some depress, and so forth. But the terms introduced with this object by Sharpey Schafer and more recently by Gley have not yet at any rate passed into general usage. Speaking of our French colleague, Professor E. Gley, reminds me that the term "internal secretion" was first employed by another great Frenchman, Claude Bernard, in relation to the liver's important work in pouring sugar into the blood stream at a steady pace. In most cases the index pointing the way to discovery has been the result of removing the organ and of injecting extracts of it into the blood and noting the results. Professor Gley has recently in one of his published discourses laid down the conditions which must be fulfilled in order that a gland may be admitted to the class of endocrine organs. He very properly decries trust being placed merely upon the results of ablation or the effects of injecting extracts. In addition, there are three main conditions which must be conformed to in order that a gland may be enrolled within this category: first, the anatomical—that is, the absence of a duct; secondly, the chemical, the recognition in the venous blood of such organs of a specific chemical product; and thirdly, the physiological, the possession by the venous blood of specific physiological properties, and this last is, of course, the superlative test. He takes the work of Bayliss and Starling on secretin as an example; it was not until Fleig, and Enriquez and Hallion actually worked with the venous blood coming from the duodenum that the probability of the truth of Bayliss and Starling's views founded upon the results of injection of duodenal extracts was rendered a certainty.

Professor Gley has done good service not only by his own experimental work, but in pointing out the way in which work on this subject must be continued. For we must confess that up till now our conclusions in reference to many of the endocrine glands do not rest on experiments which fulfil all of Gley's conditions. We must further recognise that it does not follow that because most of these ductless organs form internal secretions, all of them do so. Nature seldom works in one pattern, but her modus operandi varies. The parathyroids, for example, probably form no substance useful to the rest of the body's machinery, but probably act by removing or neutralising harmful products formed elsewhere. Noël Paton and his colleagues have shown that the poison they detoxicate is a guanidine compound derived from muscular metabolism, and if this is not removed tetany is the result.

Chemical Constitution of Internal Secretions.

Restricting ourselves, however, to the truly endocrine glands, let us dwell for a moment, not on what we know, but on the gaps in our knowledge. The chemical constitution of that iodine complex which is secreted by the thyroid has been unravelled by Kendall in America. The constitution of adrenaline secreted by the suprarenal medulla is so well recognised that it has even been synthesised by laboratory processes. The composition of pituitrin secreted by the posterior lobe of the pituitary body looks as though it will be the next to yield to the chemist's manipulations. But what do we know of the internal secretion of the part of the pituitary which is probably most essential to life, or of that of the suprarenal cortex, which is certainly the most important portion of that gland, or the nature of the internal secretion of the pancreatic islets, or of the corpus luteum in the ovary, and even of secretin itself?

I mention these few hiatuses in our knowledge to illustrate how much our wisdom is in its infancy, what fields are still to be tilled, and, lest we swell with undue pride at our present accomplishments. But, whatever gland we think about, we may be sure that quite minute quantities of their various secretions are sufficient to do the necessary work, and that these infinitesimally small amounts are indispensable, not only for our well-being, but for life itself. This, at any rate, has been proven for those secretions which can be quantitatively examined. Even although our knowledge of pituitrin is still over the border, we know that extreme dilutions of pituitary extract can exert marked power in causing plain muscle to contract vigorously, and, in the case of adrenaline, one can demonstrate that the injection of a few cubic centimetres of a solution containing only one part in a million or more of neutral saline diluent will provoke marked physiological effects on heart and blood-vessels.

Other examples of organic substances which call forth physiological effects in equally minute or even more attenuated concentrations might be given; there is, for instance, an acetyl derivative of choline, one of the constituents of our body, and the powerful amine known as histamine, which may be mentioned. In anaphylaxis, also, similar infinitesimal amounts of organic substances produce gigantic effects. Such minute doses make the doses of that product of a past generation known as homœopathists seem enormous in proportion—a reflection which will awake an echo in the hearts of those who deal with radium emanations.

Endocrine Balance.

From the days when we learnt physics we doubtless remember that important natural law which states that action and reaction are equal and opposite. The law holds in the opposing activities of our hormones, and an important branch of study has been to ascertain how such opposing actions are balanced so that they work together for good. The way in which the different organs, endocrine and otherwise, act and react upon each other has been one of the most instructive and interesting outcomes of the discovery of the internal secretions themselves. I do not think one could find any other subject which has in the present day so deeply influenced medicine as the hormone conception. Instead of remaining, as many physiological discoveries have remained, dormant as praiseworthy laboratory curiosities, the application to the practical study of disease has here been immediate, and medicine, surgery, gynæcology, and the numerous specialties of practice have all been profoundly influenced by the new doctrines. Among the specialties one must particularly allude to the one represented here this evening. Those who, on the one hand, are employing in diagnosis and treatment various electrical forms of energy, and those who are similarly engaged in radiology, have recognised that they have the power of controlling and influencing the endocrine organs to form more or less of these internal secretions for the benefit of their patients. I wish I had the special knowledge to dwell for a moment on this aspect of the problem, but those who are listening to me will be able to fill in the details of this part of the picture. The discovery of radium has been one of the greatest feats of modern science, but I need not tell my hearers that this new power for good may, like the X rays, be also in unwise hands an equally powerful agent for evil. When the activity of its emanations on living cells were first demonstrated there was perhaps naturally too great confidence displayed in its ability to cure every ill, including those which, like cancer, had defied every previous effort to conquer them.

That phase is now passed and the proper place of radium in our armoury is being adjusted to the facts. History is always repeating itself, and the story of radium is a repetition of what has occurred before when startling new discoveries had been revealed to the world. In the old days of the alchemists, who sought by magic and by the help of astral and similar agencies to discover the philosopher's stone and the elixir of life, the disappointments and failures were as numerous as the attempts to discover the secret of vitality. When alchemy was replaced by more exact science new revelations were wistfully and hopefully regarded as likely to yield the long-hidden secret; two of these epochs I have already alluded to to-night, one was the discovery of galvanism in the eighteenth century, the other of radium in the twentieth.

May I digress and linger a moment to mention one more which marked a similar epoch in the seventeenth century? I allude to the discovery of phosphorus. In the early years of that century a substance was prepared by heating heavy spar with combustible organic matter (egg white and charcoal) and this substance glowed in the dark, and for many years the name phosphorus or light-bearer was given to any substance which had the same property. The actual element we now call phosphorus was prepared by Brand about 1670, and was at first made in small quantities only from animal products—namely, urine and bones. Can it be wondered at, that in those days of superstition and mysticism the discovery in animal products of a substance which burnt and emitted light without ignition was hailed as a discovery which at last had hit upon the vital principle? Phosphorus played an important part in the development of the theory of phlogiston, which soon afterwards dominated philosophic thought, but in time died like so many other theories before and since. The furore created by the discovery of phosphorus had been paralleled by the discovery of radium in recent years. Only let us congratulate ourselves that the 250 years which intervened between the two events have taught us more wisdom, and we are not so likely to repeat the hysterical enthusiasm of our ancestors.

Accessory Food Factors.

This, however, is a parenthesis which originated from my mention of the fact that hormones and all that they connote are not simply of chemical interest, but that their importance is recognised as a factor in electro-therapeutics as in other branches of medical science. I do not think I can say the same thing about the second subject I have selected to bring before you. My only excuse for so doing is that it is one on which I can venture to speak at first hand. It may not interest you as electro-therapists, though it is not devoid of importance to you as human beings, for to all living creatures the question of food is of superlative value. The particular portion of this wide problem I intend to say a few words about is one in which also the quantitatively little is qualitatively great. I allude to those substances in our diet which we term the vitamins. The word "vitamin" is not as old as the present century, and although it is not an ideal term it has come to stay, and is certainly less cumbrous than the phrase "accessory food factor," which is its synonym.

[The lecturer then gave a brief summary of our knowledge of the vitamins, and alluded to the importance of the "next to nothing" principle there. Though accurate quantitative methods are still to be devised for their estimation, one thing is perfectly certain, and that is that the requisite amount is extremely minute, and this small amount is capable of converting a useless into a useful diet. He then continued:]

Before I leave the subject of food may I unburden myself of a suggestion? Empiricism is not always to be condemned. What we call empiricism is frequently the result of past experience. As an example, take a prescription of cod-liver oil, or of butter and cream. A few years ago it would have been impossible to explain why these forms of fat are superior, we will say, to olive and vegetable margarine. The mere fact that they are better was empirical, and now the practitioner has been fully justified, and research at last has told us the explanation—namely, the existence in the fats, which are the more valuable for remedying malnutrition, of a health-giving vitamin.

Empirical Experience and Scientific Foundation.

May not this in the future be repeated? If you
high blood pressure, why does your medical
you you may take fish and poultry and eggs,
you must abstain from beef and mutton? I can
a sceptical and argumentative physiologist
"Why? The materials you mention and I am
to take or refrain from taking are all in the
posed of protein, and surely it is not physiol-

give me such futile advice." My answer to this would be, "True it is not explicable yet on physiological grounds. It is the mere result of empirical experience. But wait a few years, and it is quite on the cards that by that time science may have stepped in and explained the puzzle, just as a few years ago it was able to explain why cod-liver oil is better than olive oil." There is probably in the harmful meats some hitherto unrecognised principle, unrecognised because it is present in minute quantities; or it may be the absence of an indispensable material. It is one of the "next to nothings," but it makes all the difference. "There is one kind of flesh of men, another flesh of beasts, another of fishes, and another of birds." I wonder if St. Paul ever imagined these pregnant words contained more than what he intended to convey by them?

[The third topic the lecturer selected to illustrate the importance of attention to apparently insignificant minutiæ was that of the capillary circulation, a subject which rose into importance during the war in relation to "shock." Here, again, especially in some forms of secondary shock where actual hæmorrhage may have been insignificant, but where crushed tissues were the usual accompaniment, it seems inevitable to accept the views urged by Dale and others that it is a toxæmic condition. The poison is produced from tissue breakdown, and operates by reducing capillary tone, so that the blood is stagnant and side-tracked in the capillary lake. Whether histamine, which certainly produces a shock-like state in this way, is the actual poison in secondary traumatic shock, or the only poison, is a question still to be answered. But, whatever the poison is, it is one of which a very small quantity produces a very large result.]

In conclusion, I must thank you for the patience you have exhibited in listening to me for so long. I wish I could have chosen a subject, or subjects, more akin to your own specialty. But if anything I have said in my disjointed remarks will help you to realise how widespread is the importance of the infinitely little my task will not have been in vain.

CONGENITAL SYPHILIS.[1]

BY HERBERT MORLEY FLETCHER, M.D. CANTAB., F.R.C.P. LOND.,

PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

IN reopening the discussion on congenital syphilis I propose to follow in the main the line taken by Sir Humphry Rolleston in his suggestive address.[2]

I should like first to make a few remarks on the *prevalence* of the disease and on its type as we see it at the present time. In one of the widely read English books on the diseases of children the author states that congenital syphilis is a *rare* disease. With this, I think, few of us can agree, and if Sir Humphry Rolleston's interesting suggestions as to its relationship to lesions of the endocrine glands can be established as facts the disease will assume an even greater importance than it previously possessed. Possibly the discrepancy of opinion as to the prevalence of the disease may be explained by a gradual change in type.

I venture to suggest that congenital syphilis in London has undergone considerable modification in type during the past 25 years—at least that is my personal experience. The number of infants with frank manifestations of syphilis, skin eruptions, rhagades, condylomata, &c., is less than it was. This does not imply that the case-frequency of the disease has diminished, but that there has been a gradual change of type, and it seems to have become increasingly rare to see the syphilitic infant as described in the text-books. It is true that I do not now see the same number of infants as I did 25 years ago and allowance must be made for this. Also many syphilitic children are sent to skin departments, who in former years would have been treated on the medical side of a hospital. But from inquiries made, there would appear to be grounds for believing that the type of disease in infants as it is seen at present in London does not seem to be so severe as formerly it was. This might be explained in two ways: (1) that the infection is of a milder type; or (2) that resistance to the infection is gradually increasing or changing in some way. It would be of value to have information as to the experience of others on this point.

Following the line of discussion laid down by Sir Humphry Rolleston, I propose to confine my remarks to three points: (1) the Wassermann reaction; (2) the influence of congenital syphilis on other diseases; (3) the influence of congenital syphilis on certain organs, particularly the kidney.

1. *Wassermann Reaction*.

There can be little question at the present time as to the value of the Wassermann reaction as carried out by a competent pathologist. Sir Humphry Rolleston, Dr. L. Findlay, and Dr. D. Nabarro have already discussed this from different points of view. It is generally agreed that a positive reaction in a child, either with or without stigmata, should indicate the necessity for active treatment which should be continued until the reaction becomes negative. A negative reaction, whether as the result of treatment or not, does not necessarily mean that the disease has died out. Both in children and adults one repeatedly sees cases in which a definitely positive reaction becomes negative after treatment and again becomes positive after lapse of time.

A negative reaction may be present in the following circumstances: (1) infection has not been incurred; (2) the infection may have completely died out, though it may have caused pathological changes or disturbance of function in various organs; (3) spirochætes may be lurking in a quiescent state in some tissue or organ of the body, antibodies not being produced; (4) the spirochætes may have undergone some change of state, such as a granular stage, which was referred to by Dr. A. Routh.

As to the value of a provocative dose of salvarsan in cases giving a negative reaction, I have not had a sufficiently large experience, but I may say that not in a single instance have I seen a positive reaction follow a provocative injection. (It will be interesting to hear the experience of others on this point.)

Sir Humphry Rolleston made a valuable suggestion in pointing out the advisability of examining in doubtful cases the Wassermann reaction in both blood and cerebro-spinal fluid. There can be no doubt as to the importance of this procedure, though it is more difficult to carry out with children than with adults, as anæsthesia so often has to be employed in the young. Personally I have never met with a positive reaction in the cerebro-spinal fluid of a child in which the blood reaction was not also positive.

The problem of the Wassermann reaction cannot be solved by the clinicians, and must be left in the hands of the laboratory workers for much further investigation.

2. *Congenital Syphilis and its Relation to Other Infective Disease.*

Resistance to infection is lowered in syphilitic children, especially in the first few years of life. This is generally recognised as regards the acute infections. With these, however, I do not intend to deal, but to confine myself to the association of syphilis and tuberculosis. These diseases may be regarded as the two commonest chronic infections of infancy and childhood, and it would be surprising if they were not frequently met with in the same subject. At the same time I do not think the association of these diseases is sufficiently recognised. Lymphadenitis is the form of tuberculous disease I have seen most frequently in syphilitic children, mostly affecting the cervical glands, which in some cases had been treated by operation. The cases presented the characteristic appearances of tuberculous glands: caseation, skin involvement, &c. The interesting point about these cases in which syphilitic stigmata had been previously overlooked was the very marked improvement which followed active antisyphilitic treatment. Two cases in older children which I saw with

[1] A paper read before the Section for the Study of Disease in Children, Royal Society of Medicine, on March 16th, 1921.

[2] THE LANCET, March 5th, p. 471.

Dr. H. G. Adamson had enlarged cervical glands (with partial excision in one case) and exhibited cutaneous rashes of the tuberculide variety described as Bazin's disease (dermatitis scrophulosorum induratum). The Wassermann reaction was positive in both. Anti-syphilitic treatment brought about a marked improvement in the tuberculous glands and the skin lesions which had not been affected by other forms of treatment. *The same improvement, as the result of treatment of the syphilis, may occur in syphilitic adults suffering from pulmonary tuberculosis.*

I mention these facts in order to draw attention to an association of disease which, I think, is often overlooked. In tuberculous cases in which the family history is suggestive of syphilis or in which stigmata are present, however slightly, the Wassermann reaction should be employed. *Treatment of the syphilis may bring about a far more rapid improvement of the tuberculous lesion than would be possible without it.*

3. *The Influence of Congenital Syphilis on Certain Organs of the Body, especially the Kidneys.*

One of the most striking features of congenital syphilis is the widespread nature of the lesions it produces. No tissue or organ of the body is immune. The internal and external secretory organs are those with which we are now concerned, and each one of these is liable to undergo definite pathological changes which have been fully described. Sir Humphry Rolleston suggested that the changes in the endocrine glands brought about by congenital syphilis may be responsible for many and varied conditions, such as dyspituitarism, some of the obscure bony diseases, lipodystrophia, &c. With the means at our disposal it seems equally difficult to prove or to disprove this point. In the great majority of cases of such diseases of the endocrine glands the Wassermann reaction is negative and stigmata are absent. But damage may have been caused by a syphilitic infection which has died out and which later may bring about a diminution of activity of the affected gland or glands. But further *evidence must be brought forward before we can ascribe a syphilitic origin to the impaired functions of these glands.*

We are perhaps on more secure ground when we consider the external secretory organs, especially the liver and kidneys. With the liver I do not propose to deal as probably the changes due to syphilis in this organ have been more fully investigated than those in any other gland. It is somewhat remarkable that comparatively little investigation has been made as to the early and late effects of congenital syphilis on the kidneys.

Sir Humphry Rolleston has suggested that the extensive renal changes found in the group of cases associated with dwarfism or infantilism are due to syphilis. The general consensus of opinion at the present time would seem to be opposed to this view. I might mention that the last case of this description brought by me before the Royal Society of Medicine gave a negative Wassermann reaction in both the blood and cerebro-spinal fluid.

It might be urged that the kidney lesions are due to a syphilitic infection which has died out. Against this I would point out that the changes in the kidneys are always very marked and indicate some infective or toxic agent of considerable virulence. Had syphilis been the cause one would expect other organs to have been affected to a greater or less degree, whereas it is significant that the kidneys alone exhibit changes, except for the secondary changes in the cardio-vascular system.

The morbid changes found in the congenital syphilitic kidney may be briefly summarised as follows:—

1. In the fœtus—stillborn at term, and abortions. In these there is often evidence of arrested development. Groups of cells of embryonal type surrounded by normally developed tissue and a varying degree of small-cell infiltration of the cortex.

2. *In infants.* Similar changes may be present, but sclerosis may have begun. These areas of infiltration adjoining zones of proliferating connective-tissue cells and bands of fibrous tissue. Queslier[3] states that in most cases the lesions, whether old or recent, are arranged as islets with normal areas between them. They are situated mostly in the cortex, and the kidneys are often unequally affected.

3. In older children the sclerosis is more diffuse and the capsule is adherent; the weight of the kidneys is generally unequal and is diminished.

This is a very brief summary of the more severe types of renal disease due to congenital syphilis; it is only reasonable to believe that there are milder degrees of involvement. Also, as in the case of the liver, as the result of treatment recovery may take place, but the organs may be rendered unduly liable to disturbance later on in life by comparatively slight causes. Rose Bradford and others have suggested that cases of so-called idiopathic nephritis may be due to syphilis as a *predisposing cause. If this be true, the influence of* syphilis may be explained by the supposition that the spirochætes, although they have died out, have left behind a damaged organ or one which is peculiarly susceptible. A mild attack of one of the specific fevers, such as varicella, in a child known to be syphilitic may be followed by an acute nephritis.

Hutinel[4] has drawn attention to the vulnerability of the kidney in congenital syphilis, and has pointed out the liability to relapse which these cases of nephritis may exhibit. In some the exciting cause may be a slight attack of tonsillitis or of impetigo. Syphilis may be a factor in some of the not uncommon cases of intermittent albuminuria of childhood. As in the case of the liver, there may be a long latent period (during which the spirochætes may be present but inactive), and in these signs of nephritis make their appearance about the time of puberty as the result of some other infective or distributing cause which may rouse the spirochætes again into activity.

Time will not permit further consideration of these clinical manifestations, but my object is to draw attention to the very important relationship congenital syphilis may bear to kidney disease, and to urge that the necessity of determining whether syphilis is a factor *should be borne in mind in dealing with doubtful cases* of renal disease in children.

The *lungs* also may be affected by congenital syphilis. The association with tuberculosis has been referred to, and I will say no more on this point. Pneumonia alba is a rare massive condition of the lung found in new-born infants, and so far as I know has no special clinical interest. But syphilis may also give rise to a slighter degree of infiltration compatible with longer life, which may lead to pulmonary fibrosis and, according to Still and others, to bronchiectasis. It may well be that in cases of latent syphilis an attack of broncho-pneumonia or acute bronchitis may stimulate the resting spirochætes into action and fibrosis or bronchiectasis ultimately result. It would be interesting to know what proportion of cases of fibrosis of the lung give a positive Wassermann reaction.

Conclusion.

In conclusion, a few words about *treatment.* It seems to be generally agreed that intravenous injections of one or other of the modern arsenical compounds should be combined with the administration of mercury either by the skin or mouth. I have been impressed on several occasions with the small doses of mercury given by the mouth by some practitioners. *Infants and children are remarkably tolerant* of this drug, and I do not think that the best results are obtained unless comparatively large doses are given: beginning with ½ gr. doses of pulv. hyd. c. creta twice daily, then thrice, and gradually increasing this up to 1½ gr. thrice daily. This should not be followed by any ill-effects. My late colleague, Dr. Eustace Smith, was in the habit of giving considerably larger doses than these. Should the drug cause diarrhœa, as it may do, though rarely, when first given, an equal quantity of aromatic chalk powder combined with it will prevent any looseness of the bowels.

POST-SALVARSAN JAUNDICE.

BY A. T. TODD, O.B.E., M.B. EDIN., M.R.C.P. LOND.,
MAJOR, R.A.M.C.; CONSULTANT PHYSICIAN, RHINE FORCES.

DATING from October, 1920, a small epidemic of jaundice following treatment of syphilis by novarsenobillon has been noted in the Rhine army. The first case of the series died five days after admission to hospital, and was diagnosed acute yellow atrophy at the autopsy. Several more cases, clinically similar, were admitted shortly after this occurrence, and I was led to examine for evidence of hepatic disturbance and acidosis. The findings were so constant, had so much bearing upon prognosis and treatment, and were so different from the findings in jaundice from other causes that I think they may be of interest.

The series comprises 24 cases of "914" jaundice, and as controls 15 cases of jaundice in patients who were non-syphilitic and had not had any arsenical treatment. I do not propose to discuss the exciting cause of the jaundice, for that has been considered already by several observers, who conclude that it is the arsenical radicle of novarsenobillon. In the literature at my disposal there is only one dissentient on this point, E. G. Ffrench,[1] who concludes that the jaundice is due to syphilis itself in some cases, and that it occurs with some frequency in patients who have received no "914" or other arsenical preparation. However, H. D. Rolleston[2] states that jaundice in secondary syphilis is rare, and quotes figures of Werner and Goldstein showing that jaundice occurs only 77 times in 23,261 cases of syphilis before the introduction of salvarsan. Nicaud,[3] G. E. Strathy, C. H. V. Smith and B. Hannah,[4] and R. Hallam,[5] conclude that the jaundice is due to arsenic. Moreover, the jaundice of secondary syphilis is said to be hæmolytic in type[6]; Nicaud[7] determined the fragility of the red blood corpuscles in a series of his cases, and found an increase of resistance; in two cases of the present series I tested the fragility and found definite increase. The treatment of jaundice due to syphilis is that of syphilis (Rolleston); in "914" cases further exhibition of arsenical preparations aggravates the condition. Moreover, if the condition were due to active syphilis a positive Wassermann reaction should be present; this was not found to be the case in the present series. It has not yet been proved whether the toxicity is due to arsenic properly combined as novarsenobillon, or whether it is due to some arsenical impurity; Hallam[8] could find no impurity in the samples supplied to him in his series.

No case of this jaundice appeared during the period March–September, 1920. The occurrence of the epidemic coincided with the onset of cold weather. The explanation of this is probably twofold: (a) the seasonal incidence of afebrile jaundice has been shown to reach its maximum in the winter months,[9] and (b) a heavier burden is thrown upon an embarrassed liver by the winter diet rich in fats and proteins. The time of onset of symptoms relative to the dosage of "914" received shows no difference from what has previously been observed. The smallest total dosage of "914" in this series was 4·05 g., the largest, 12·15 g. The time of onset after the last injection varies from one day to 17 weeks, the average being 10 weeks. Nicaud[10] divides "914" jaundice into early and late types—that is, occurring soon after small or late after large dosages. He came to the conclusion that the early cases had a more serious prognosis. In this series such a division could not be made; some of the late cases were mild, some severe, and vice versa.

The investigations made include clinical findings and narration of symptoms, as these differ from those found in catarrhal jaundice, and are therefore of importance in differential diagnosis. The urinary investigations comprise examination of the amount, acidity, presence of albumin, casts, sugar, acetone, deposit of leucin and tyrosin, bile pigments and acids, urobilin, percentage of urea, estimation of ammonia, and the ammonia-urea gen ratio. The diastase was estimated in each case from time to time. These examinations were made daily until convalescence was established. All the quantitative and most of the qualitative examinations were made by myself with the same apparatus throughout.

Morbid Anatomy.

In brief, the morbid anatomy appears to be a hepatitis leading to fatty degeneration (v. Nicaud's early autopsy[11]), followed by cell death and compensatory fibrosis of periportal distribution. The fibrosis would appear to be responsible for the further atrophy and shrinkage of the liver. Next in severity to the liver the kidneys are concerned, and show a marked degeneration and atrophy of the tubular epithelium. Fatty degeneration of most tissues is present. Hæmorrhages into brain, lungs, pleura, pericardium, and peritoneum are common in fatal cases. The liver shrinkage in life was demonstrated in 30 cases by X ray measurement.[12] In addition, Strauss[13] describes ascites in one fatal case.

In an early case it would be expected that a normal-sized, or rather enlarged, liver would be encountered, the enlargement being due to one or more of the following conditions: vascular engorgement, fatty degeneration, or small-celled infiltration; acidosis should be present from defective protein metabolism. As the condition progresses to convalescence or death, shrinkage would result from diminution of the hepatitis or further atrophy. It will be seen in the next section that these conceptions are justified.

Symptoms.

The presenting symptoms as compared with those of catarrhal jaundice appear in Table I.

TABLE I.

Type.	No. of cases.	Nausea.	Vomiting.	Headache.	Epigastric pain.	Anorexia.	Sore throat.	Pruritus.	Epistaxis.	Jaundice.	Dimness of vision.
		%	%	%	%	%	%	%	%	%	%
"914 jaundice" ...	24	33	22	41	58	45	9	13	0	55	4
Catarrhal jaundice	15	67	53	33	44	53	0	16	0	48	0

The character of the symptoms in the two classes show no marked differences, with the exception of abdominal pain, which in the "914" group showed no relationship to food; in three cases, all showing definite evidence of liver enlargement, the pain was dependent upon posture, being aggravated by lying upon the left side. The abdominal, just as the cephalic pain was not well localised. Shoulder pain was not observed. Dimness of vision occurred in the fatal case three days before death.

Clinical Findings.

The clinical findings in the two groups appear in Table II.

TABLE II.

Type.	Pharyngitis.	Desquamation.	Palpable spleen.	Large, palpable liver.	"Tender" liver.	Epigastric tenderness.	Icterus.	Erythema.	Somnolence.	Diminution of ankle-jerks.
	%	%	%	%	%	%	%	%	%	%
"914"	9	30	5	38	33	50	100	9	22	9
Catarrhal	0	7	13	7	13	27	100	0	0	0

Pyrexia was not observed; the one fatal case showed a subnormal temperature. The skin desquamation affected chiefly the extensor surfaces of the limbs; in a few cases the trunk, especially the chest, showed scaling; there was no associated dermatitis.

Condition of liver.—In the "914" group the liver was definitely palpable and enlarged in 38 per cent. of the cases; the real percentage is certainly higher, for the pain evoked by palpation was so severe, or caused so much boarding of the abdominal muscles, that the attempt was given up. In all these cases the superior liver dullness was normal and the consistence of the liver was distinctly hard, in some cases giving the impression of wood; in about one-third of the cases there was pain or discomfort, as the sharp lower edge slipped over the palpating thumb (procédé de pouce). In one case there was definite evidence of a small-sized liver; in this case fatty casts were found in the urine. In an important percentage of the "914" group the liver was enlarged and altered in consistence.

The *erythema* noted was similar to that observed by Sicard.[14] Absence of Achilles jerk is regarded by Sicard as an important early sign or arsenical neuritis; diminution on one side was noted, no complete absence of ankle-jerks occurred. The eye-grounds of several severe cases were examined by the ophthalmological specialist, Captain Pringle, R.A.M.C., who found nothing abnormal. The liver condition changes with the progress of the case; in three cases only did the enlargement persist in convalescence, and these cases were three of the most severe. When enlargement persists it may be assumed that the cirrhotic changes are permanent.

Somnolence was noted only when distinctly more marked than the depression and lethargy common in other forms of jaundice. The one fatal case developed somnolence after two days in hospital; it was accompanied by delirium and rapidly deepened to coma. The same somnolence was noted in the earlier cases of the series by the M.O. in charge of the medical wards, who directed my attention to them as possible cases of acute yellow atrophy. Instructions were then sent out to all M.O.'s of units to watch for cases of jaundice in men who had had treatment for syphilis, and to send cases to hospital when discovered. The result was that, with one or two exceptions, the later cases were much milder, and somnolence was not noted again. This somnolence, I suspected, was due to disturbed hepatic metabolism; I accordingly examined for a resulting acidosis. Strathy[15] suspected acidosis, but gives no figures. The estimation of acidosis was accomplished by comparing the ratio of the ammonia nitrogen to that of the urea. According to Panton,[16] "A reliable guide to the extent of the acidosis can be obtained from a comparison of the ammonia and urea nitrogen." Samples of normal urine, of urine of diabetes, of catarrhal jaundice, and of patients who had had much "914" treatment were examined, and the results of the catarrhal cases are included and are referred to as "jaundice controls."

Urinary Findings.

It is regretted that no urinary examination was made in the fatal case; this case occurred in my absence. To detail the findings in each case would require too much space; amongst other examinations the ammonia-urea nitrogen ratio was determined 500 times. Many of the results may be summarised and dismissed briefly. The urine of each patient was collected in a receptacle stored in a cool place; all examinations were made with complete 24 hours' specimens.

Amount.—Usually diminished, the average being 45½ fluid ounces during the first complete 24 hours. The diminution appeared to be proportionate to the severity of the case. On the fifth day the urine averaged 59 fluid ounces. Jaundice controls (catarrhal or apyrectic jaundice) showed like amounts, 45 ounces on admission, increasing to 66 ounces on the fifth day.

Acidity.—High on admission, requiring 34·5 c.cm. decinormal caustic soda per cent. for neutralisation. This diminished rapidly, and on the fifth day averaged 15·5 c.cm. Controls averaged 22 c.cm. per cent. on admission, and 14·1 c.cm. on the fifth day.

Albumin.—Present in 14 per cent. of the cases. It disappeared in convalescence, was slight in amount, never more than a trace being noted. The jaundice controls showed no albumin.

Bile pigment.—Gmelin's test was positive in 92 per cent. of the cases on admission.

Urobilin.—Present in the 8 per cent. of the cases in which bile pigment was absent. Schlesinger's test and the test of Morel and Policard[17] were applied in each case. Urobilin was generally found present several days after bile pigment had disappeared. Urobilin, unaccompanied by bile pigment, was not found in the catarrhal control, though its occurrence has been noted.[18]

Bile acids.—Hay's test was performed in every case until the severe and mild cases alike failed to give a positive reaction.

Deposit.—Detailed notes were not kept in all cases. Sediment usually consisted of amorphous urates; uric acid crystals were occasionally, and oxalate crystals were frequently, noted. Pus corpuscles were commonly present, and on three occasions showed well-marked, deeply stained globules with osmic acid. No blood was noted. Oxalate crystals were also found in many of the jaundice controls.

Casts.—Present in 11 per cent.; usually granular or hyaline. Fatty casts were sought in each case, but were found in one only.

Leucin and tyrosin.—Sought in the deposit of each case but never found. Precipitation methods were not employed.

Sugar.—No case showed presence of reducing substances.

Acetone.—Not found.

Urea.—The percentage on admission was high, the average being 2·4 per cent. Jaundice controls averaged 1·63 per cent. In both classes the urea percentage rapidly diminished owing to the special diet given.

Ammonia-urea nitrogen ratio.—The formalin method, as described by Panton, was employed for the ammonia estimation; for the urea the hydrobromite method. For the former 20 c.cm. of urine were taken, and for the latter 4 c.cm. The calculation of the contained nitrogen is simplified by multiplying the number of cubic centimetres of decinormal sodium hydroxide solution used, after adding the neutral formalin, by 14; the number of cubic centimetres of nitrogen evolved is multiplied by 58·33, the latter constant being worked out on the basis that 16 c.cm. nitrogen correspond to 1 per cent. urea.[19] This figure is rather high; 15 c.cm. are given by Plimmer.[20] The division of the former figure into the latter gives the ratio—ammonia nit. : urea nit. :: 1 : x. For brevity the latter figure only is given. On the day of admission the ratio averages 9·35, the lowest being 6·0 and the highest 15·0. "Under normal conditions the ammonia nitrogen is about one-twentieth of the urea nitrogen, and in conditions associated with acidosis it may rise to one-fourth. A rise in the ammonia nitrogen to one-tenth of the urea nitrogen is definite evidence of acidosis."[21] Seventy-one per cent. of the cases show a ratio of less than 10—i.e., one-tenth—on the day of admission. Taking the average of the clinically severe cases, the ratio was found to be 8·1; the average of the cases showing somnolence is 8·0. The average ratio after four days in hospital was found to be 22·0—i.e., one twenty-second. Some of the cases did not show an acidosis on the day of admission, but the ratio of ammonia nit. : urea nit., in some cases dropped below the acidosis level on the second, third, or fourth day. At some time during the acute stage of the illness acidosis was determined in 80 per cent. of the cases, and was present in all but the slight cases.

In the jaundice controls the average ratio on admission was 16·3. After five days it averaged 22·0. In only one case did the figure fall below 10·0, and this was regarded as being due to ammoniacal fermentation, for the acidity was very low, and triple phosphates were found in the deposit. It should be noted here that all the cases, controls also, were treated in the same ward, had the same diet, and the same medicinal treatment, with the exception that in one or two of the catarrhal group pill fel bovini was given t.d.s.

I am aware that catarrhal jaundice, in some schools at least, is no longer regarded as merely a symptom-complex brought about by the damming up of bile by an acute stenosis of the bile-ducts due to catarrhal cholangitis, but as a lesion of the hepatic cells, which interferes with the hepatic function as a whole.[22] But the figures given above appear to show that the hepatic function is much more severely embarrassed in the "914" cases.

Urinary diastase.—This was measured partly to determine whether there was evidence of pancreatic involvement, and partly because it was considered possible that differential diagnosis in catarrhal cases might be facilitated; for a pancreatic origin in certain cases of catarrhal jaundice is considered by Rolleston. An associated catarrh of the duct of Wirsung might accompany that of the common bile-duct. The Wohlgemuth technique as described by Wallis[23] was followed; in all 140 estimations were made. Figures on the whole show an increased amount of diastase; in 42 per cent. of the cases the figure reached or exceeded 40; the highest figure noted was 100 units, which fell to 20 units within seven days. Figures of 50-60 units were fairly common. In 19 per cent. of the cases the figure dropped below 10 units at some time; the lowest figure reached was 6 units, but this is regarded as the lowest normal limit by Maclean and Russell.[24] The remaining 39 per cent. gave normal diastase figures throughout the illness—i.e., 10-30 units. This increase is of interest, as it may demonstrate pancreatic involvement or may be regarded as further evidence of hepatic embarrassment; for an increase of the diastase has been found constantly in the toxæmias of pregnancy,[25] in which condition hepatic involvement is generally conceded. In all cases where the diastase showed normal values the figure became normal in a few days. This examination was found to be of little value in differential diagnosis, for a similar increase, varying between 40 and 80 units, was found in 28 per cent. of the jaundice controls; this is further evidence for the presence of pancreatic changes in catarrhal jaundice.

The urinary findings justify the opinion that a lesion of the liver tissue is present and that an acidosis results; for 80 per cent. of the cases showed evidence of acidosis at some period of the illness. Moreover, the degree of acidosis was proportional to the severity of the clinical findings; also the acidosis disappeared as the other symptoms subsided.

Course of the Illness.

The average of the cases shows that the period spent under close observation was 22 days; about three days added to this gives the average time spent in hospital. The last day after admission on which acidosis was present averaged the fourth day. No case was discharged from hospital until he had been on the full diet for a week, and had performed some light duty. So far no relapses have occurred.

Prognosis.

The case mortality is difficult to determine. From the literature quoted I have been able to obtain figures in 141 cases; amongst these 23 deaths are recorded, giving a mortality of 16·3 per cent. This figure may be too high, for, possibly, some early deaths, not due to hepatitis, are included. On the other hand, it is highly probable that some of the fatalities have been described as acute yellow atrophy, for this condition, formerly a great rarity, appears to be fairly common at present, and comparatively numerous cases are described in the current European literature. The present series, which is not included in the above figure, shows a mortality of 4·1 per cent.—i.e., one case, the first of the series, who did not receive any specific treatment. Series of cases show very variable mortality rates; both in Hallam's and Nicaud's series no deaths are recorded.

Treatment.

All the cases were kept in bed until chicken diet was ordered. Fluids were given freely, especially imperial drink. The only routine drug treatment given was sod. bicarb. 60 grains t.d.s. Laxatives were ordered when required. For 24 hours after admission full diet and no treatment was given in order that the gravity of the case could be determined. After this the patient was put on the following diets, one after another, as the urinary and clinical findings improved: (1) starch diet: in this proteins and fat are excluded, the diet consisting of bread, fruit, boiled vegetables, milk puddings (made with very little milk), jelly (as a protein sparer), and tea without milk; (2) fish diet: the addition of boiled fish being made to the starch diet; (3) fish and eggs: one or two eggs per diem in addition to the fish; (4) chicken diet: the ordinary chicken diet of the hospitals, the patient being allowed out of bed; (5) ordinary diet: when this was given the patient was encouraged to help in the ward. It may here be noted that the recovery of the jaundice controls appeared to be accelerated by this treatment.

My thanks are due to the D.D.M.S., Rhine Forces, for issuing instructions to all M.O.'s of unit and otherwise facilitating the investigations; also to Major E. F. Bashford, O.B.E., R.A.M.C. (T.C.), D.A.D. Pathology, for permission to perform examinations in the laboratory.

GENERALIA ON THE
LOUSE PROBLEM AT THE WESTERN FRONT.

BY A. D. PEACOCK, M.Sc.,
ARMSTRONG COLLEGE, UNIVERSITY OF DURHAM.

IN order to round off my records of the results of about three and a half years' continuous work, mostly in Flanders, on various aspects of the louse problem, I publish the following few remaining generalia from my notebooks. They are somewhat belated, but many post-war duties have prevented their collation.

Viability of Lice.

Through the kindness of Mr. A. W. Bacot, of the Lister Institute of Preventive Medicine, a supply of nits and about 300 lice of all ages were forwarded to me in France for certain experiments. The eggs were attached to small pieces of khaki cloth upon which the insects were at liberty to cling and crawl. All were dispatched in a round wooden pill-box $1\frac{1}{2}$ inches in diameter and of the same depth. The insects had been given opportunity to feed at about 4 P.M. on Oct. 22nd, 1918, and were then packed and placed in the post. They reached the laboratory in France on Oct. 29th, and, with the exception of a few which were set aside for viability experiments, were allowed to feed at 2 P.M. The survivors which fed numbered 138—approximately one-half of the original number dispatched—were of all ages except, of course, newly hatched specimens. Thus a fast of 6 days 22 hours apart from the human host, at an unknown temperature in the post, was well within the powers of the insects. Similar observations to this have been recorded by many observers, but the two following experiments present new features.

Experiment 1.

Oct. 22nd, 1918, 4 P.M.: Lice given opportunity to feed by Mr. Bacot.

Oct. 29th, 11.30 A.M.: 2 nymphs and 1 larva in second instar separated and placed in incubator at 28° C.

Oct. 31st, 10 A.M.: All fed after a little effort, one standing on its head to do so. 2.30 P.M. and 6.30 P.M.: All fed; kept in an incubator at 28° C. between feeds.

Nov. 1st, 9.15 A.M.: Only 1 nymph fed; the second nymph still alive, but too feeble to feed though given 30 minutes to do so; killed. Larva dead. 6.30 P.M.: Survivor fed.

Nov. 2nd, 10 A.M., 3 P.M., and 6.45 P.M.: Survivor fed.

Nov. 3rd, 9.15 A.M. and 6.30 P.M.: Survivor fed.

Nov. 4th, 11.15 A.M.: Survivor did not feed; incubator had failed, and louse exposed to room temperature for several hours. (Temperature not noted.) 6.30 P.M.: Appears nearly dead—ruptured.

Experiment 2.

Oct. 22nd, 1918, 4 P.M.: Lice given opportunity to feed.

Oct. 29th, 11.30 A.M.: 3 nymphs and 2 larvæ in the second instar separated and placed in incubator at 28° C.

Oct. 31st, 10 A.M.: Lice removed and kept on bench at about 15° C.; still able to crawl feebly. 5.15 P.M.: Given opportunity to feed; the 3 nymphs settled and fed almost immediately; one larva was more tardy in feeding, while the other crawled around feebly before settling, and did not feed till some time after; the larvæ were the feeblest of all. Subsequently, between feeds, kept in incubator at 28° C.

Nov. 1st, 9.15 A.M.: 4 fed; one larva failed to feed after 30 minutes and subsequently died. 6.30 P.M.: 4 fed.

Nov. 2nd, 10 A.M.: 3 nymphs fed. The larva fell into a bowl which had been wiped with strong cresol and never fed afterwards. 3 P.M. and 6.45 P.M.: 3 survivors fed.

Nov. 3rd and 5th: All fed twice a day, morning and evening.

Nov. 6th: All appear perfectly healthy; added to stock.

These experiments and observations show: (1) that nymphs and larvæ in the second instar may survive a fast and separation from the human host of 9 days 2 hours—$6\frac{22}{24}$ days in the post, $1\frac{22}{24}$ days in an incubator at 28° C., and $0\frac{7}{24}$ day in a laboratory at 15° C.; (2) that, moreover, though very enfeebled after their fast, they still had strength enough to feed and subsequently recover; (3) that this period of fasting and separation from the human host approximates very closely to the limits of endurance of the insects.

These conclusions are of interest because, to my knowledge, no other records show for similar conditions quite such a high viability for the louse. It is of interest, too, that these hardy specimens were nymphs, and presumably about the prime of life.

A Clothing Repair Depôt.

Compared with that of the bug or flea the viability of the louse is very low; this fortunate fact is well illustrated as follows.

In July, 1918, Lieutenant-Colonel Statham, A.D.M.S., Paris Area, took me to the repair depôt for clothing organised by the British Army Ordnance Department in Paris, where Captain Thompson, A.O.D., kindly demonstrated the routine of the institution and, in reply to questions, furnished much interesting information on the infested condition and treatment of the garments received. To this depôt were returned vast quantities of soiled, discarded and salved garments of the British armies in France to be dealt with appropriately. The number of garments received per year was estimated at 2,000,000. Some were only fit for burning, but large numbers were renovated and re-issued for service. During the renovation process the first operation after sorting was the inspection and segregation of those garments which had been excessively highly infested. Such articles showed the usual characteristic appearance—innumerable nits packed like large sand grains along the lines of the seams and the creases, interspersed with lice of all sizes. The next operation was carried out by old women who, by means of knives, scraped the egg masses away from the cloth. The points of interest, upon which the old women and Captain Thompson were most emphatic, are, first, that sorters and scrapers never became infested and, secondly, that they would not have taken on such employment had they felt that there was any risk of infestation. Evidently the period of separation from the human host, an indeterminate period largely spent in transit from the front to the base, was sufficiently long to kill both lice and nits. Such being the case, no special methods of disinfestation were employed, the articles being laundered in the usual way.

This affords an excellent illustration of the fact that practical and extremely valuable services were dependent upon the relatively low viability of the louse!

"Dangerous Carriers."

The proportion of articles scraped varied with the type of garment—e.g., of the riding breeches 60 per cent. were so treated, of the tunics 7½ per cent., and of the underclothing 5 per cent. In drawing any conclusions as to the degree of lousiness of the troops from these figures it should be borne in mind that no records existed of the number of times these garments had been disinfested up the line or of the degree of the last infestation before being discarded. But, taken in conjunction with my studies of the infested condition and the psychology of certain types of soldier tolerant of extreme lousiness, these comments may be advanced. The men who had worn these garments were evidently of this type—I have called them "dangerous carriers"—because no self-respecting soldier would ever permit his clothing to get into such a state either as the result of one huge visitation or from traces of a number of smaller infestations severally combated by disinfestation at various times. He would have scraped it or burnt it himself. Besides, few quartermasters would have refused an issue of new clothing to such cases. The general point of importance which issues is that my estimate that nearly 8 per cent. of infantrymen were "dangerous carriers" has received corroboration in a somewhat curious and unexpected fashion.[1]

A Note on Dissemination.

The relative importance of the various sources of dissemination have been thoroughly discussed elsewhere[2]; but, to recapitulate briefly, it may be mentioned that by far the most important source was the lousy soldier. Blankets, bedding, latrines, dug-outs, &c., were of minor significance. To illustrate the latter point I cite an experience which occurred while I was attached to the New Zealand Division in June, 1916, at Armentières.

This division had but recently arrived in France from Egypt, and I was detailed to give instructional work to it on "flies and mosquitoes." However, opportunity was taken to make certain observations on my special subject. Just previous to departure from Egypt the whole division had been thoroughly and generally disinfested by means of "Hunter's train."[3] The troops were brought practically straight to the Armentières front and certain battalions placed in the line. After about ten days of trench warfare one battalion was brought to the baths and 110 shirts were examined immediately after the men took them off. After the usual experiences with many battalions at many other baths the results were a pleasant change; a large number were louse-free, the average was only 3, and the range from 0 to 20.

Without a complete knowledge of the condition of the men prior to their entering the trenches, it is impossible to state precisely the reasons for this infestation and for its degree; but, to speak generally, the disinfestation in Egypt must have been well done, and the trains, billets, and dug-outs in France must have been only very slightly infested, which latter is the point I wish to make. These facts will appear more striking when one considers the usual condition of troops on going up into the trenches and on returning therefrom to the baths.

Proportion of Men Infested with Crab-lice.

One of the features of the louse problem which I never had full opportunity for investigating as thoroughly as it deserved was that of crab-lice (*Phthirius pubis*). Observations of infestation by such were made at various times, as, for instance, when testing the effects of insecticides upon troops, and led me to believe and state in lectures at the front that these infestations appeared to be of much commoner occurrence among troops in the fighting area than was generally supposed. Until 1918 the data were not considered as sufficiently detailed to warrant publication, but as a striking record was furnished me by Lieutenant Seaton, of the United States Medical Corps, I associate the two best of my examples with his.

1. Out of 83 men from three different infantry regiments of a certain division 4·7 per cent. were found infested with crab-lice (May, 1916).
2. Out of an experimental party of 21 men from seven different field ambulances of a certain corps 14 per cent. were infested (May, 1917).

I have no reason to believe that the condition of these men was otherwise than typical of the general condition of troops in the forward areas at these times. As the result of a meeting with me, in which the louse problem was discussed, Lieutenant Seaton took special pains to investigate the condition in regard to crab-lice of the men of a brigade of British artillery to which he was attached as medical officer. About the middle of September, 1918, he kindly gave me his report. He had physically inspected 850 men while they were on duty in the gun-pits and wagon-lines in the Ypres salient, and found the total proportion of men infested was 35 per cent. This result was based upon observations as to whether crab-lice or nits or both were present on the pubic hairs. Lieutenant Seaton also detected body-lice (*Pediculus humanus* var. *corporis*) co-existing with crab-lice, but was of opinion that the majority of cases were "crab" infestations. Where nits alone were found on the hair he had not taken any steps to ascertain to which species they belonged or whether they were alive or not. He had not classified the cases in relation to their degrees of infestation. To many this result will be somewhat surprising.

The Degree of Infestation of Combatant Troops at various times during the Campaign.

For purposes of comparison the following table, compiled in October-November, 1915, and published in a previous paper[1] is inserted:—

Proportion of men—		Proportion of men—		
Without any lice	4·9%	With 30-129 lice	11·2%	
With 1-9 lice	41·9%	„ 130-349 „ ..	4·9%	7·7% d.c.
„ 10-19 „	19·6%	„ more than 350	2·8%	
„ 20-29 „	14·7%			

d.c. = Dangerous carriers.

In order to test an insecticidal powder a certain division was visited in a rest area during May, 1916; the clothing of 85 men from three different regiments was examined and gave the following result:—

Proportion of men—		Proportion of men—	
With 1-10 lice	67·0%	With 51-100 lice .	15·3%
„ 11-50 „	10·5%	„ over 100	7·0%

During the years 1916 and 1917 I noted the condition of garments on many other occasions whilst engaged for more or less protracted periods at various [illegible] In the northern sector on the testing and stan[illegible] methods of disinfestation. The work was at divisional baths and at the large corps disinfestor at Poperinghe. Other duties prevented me from repeating my methods for obtaining data such as cited above, but I observed sufficient to convince me that these two results would still hold good. My last experiences occurred at a general hospital at a base towards the end of the fighting in October–November, 1918.

[2] A. D. Peacock: Op. cit.

[3] Nuttall, G. H. F.: Combating Lousiness among Soldiers and Civilians, Parasitology, 1918, vol. x., No. 4.

During the pursuit of a research on the relation of lice to trench fever I examined the clothing of ten men admitted sick from an adjacent machine-gun depôt. In one case only no lice were found, but there were many hundreds upon another. The lousiness of the remainder varied from 1 to 15 with an average of 6·7. The number of cases examined was certainly small, but, on the other hand, they were not specially selected. Such a condition, however, should not have existed in a highly disciplined depôt provided with a large and efficient disinfector.

I also examined the condition of the clothing of the men who had been wounded in the heavy open fighting of that period. The men, who belonged to diverse regiments and divisions, had usually spent two or three days in the train before reaching the hospital, and still wore their compaign-ing clothing. Rapid examinations of their garments were made when they reached the disinfector, and invariably showed that very few cases, if any, were louse-free, while many were highly verminous. On one occasion 34 shirts were examined more carefully and showed 11 (34·0 per cent.) louse-free, 13 (37·0 per cent.) with a few lice, while 10 (29·0 per cent.) had varying numbers of insects—50 to some hundreds—upon each of them. This, it should be remembered, resulted from the inspection of one kind of garment only. Repeated visits paid subsequently to the disinfector and more cursory examinations of the garments indicated the same state of affairs. I did not consider it necessary at these latter examinations to go into minutiæ, as my experience in such matters convinced me that the one result already mentioned was sufficiently representative.

These instances show that the pedicular condition of the combatant troops in France at the conclusion of the fighting in November, 1918, was no better than it was in November, 1915, when I obtained the first figures in regard to lousiness. In order to understand how this condition of affairs came about a brief outline of the main features of the anti-louse compaign among the British troops in France may not be without interest.

Salient Points in the History of Disinfestation at the British Western Front.

In planning an anti-louse campaign the first condition to create was a general belief that the louse could be beaten. But among combatant troops of all ranks the fatalistic tradition that the louse is an objectionable but natural and unavoidable fact of war dies hard, and, in the light of the preceding notes, it would seem that the tradition should still hold. But it holds not because the louse has defied investigation by the entomologist or because the rationale for its extermination was never outlined, but because the sound and proved suggestions of research were not followed up in the grand manner. Investigation made it perfectly plain that the louse was not endowed with occult powers, and anyone who followed the course of disinfestation experiment in France and England, and also the literature of the subject, could see that sufficient work had been performed to warrant the initiation of a bold anti-louse campaign at the beginning of 1916. But when convincing experimentation is not backed up by the application of its teachings, instructional work among lousy troops becomes counsel of perfection, and there is little hope of creating the will to defeat the insect enemy. Of course the most effective event, which would have startled the authorities into the necessary activity, would have been an epidemic of typhus at an early date in the campaign. Fortunately, perhaps, this never eventuated, and the menace of typhus as one argument for disinfestation was never of value. The discomfort of lousiness, its effect on men's rest and sleep, and the resultant depression of their physical fitness were never considered poignant reasons for disinfestation, while the more apparent effects of skin diseases, directly and indirectly traceable to lice (as well as the scabies mite) did not make sufficient appeal.

We may now follow the course of the anti-louse campaign, dealing first with the instructional side and then with the experimental. But before doing so I should like to pay tribute to the immense amount of work performed at home by Mr. A. W. Bacot, of the Lister Institute of Preventive Medicine, and Professor G. H. F. Nuttall, F.R.S., of the Quick Laboratory, Cambridge, on the problem, both of whom have assisted me many times. Their influence can only be appreciated by those who took active part in the anti-louse campaign.

(*a*) *Instructional.*—Very little organised instructional work was carried on in France until 1916, when, subsequently to the publication of various articles in the scientific journals, the War Office issued a pamphlet on the louse problem on the Western front. During the winter of 1916–17 army and corps schools of sanitation for medical officers were established, where weekly lectures on the louse problem were given as part of the curriculum. Later similar schools were instituted for non-commissioned officers and men engaged in various services on sanitary duties. In May, 1918, a "Circular Memorandum," a useful brochure on disinfestation, was issued by the Director-General of Medical Services, and a revised edition appeared in August. The practical result of these publications and lectures is difficult to assess. Ideas were disseminated and interest created, but little was accomplished which directly affected the welfare of the fighting soldier up the line. For instance, to the regimental medical officers who attended the schools, men with a thousand other regimental cares, the problem of disinfesting their men was beyond them, as they were totally unprovided with apparatus. Even had they possessed any, such as flatirons, or improvised any, as certain officers of my acquaintance did, the conditions permitted such very limited opportunities for their use that little could be accomplished.

(*b*) *Experimental.*—Consideration of the part played by "insecticides"—palliatives at the best—need not detain us long. Of the many preparations applied to the clothing and body only one emerges as promising—naphthalene. During 1914 and 1915 tests with N.C.I. powder (naphthalene 96 parts, creosote 2, and iodoform 2) showed fair success, but before a routine for its issue and use could be established the supplies failed and all subsequent efforts to obtain naphthalene in large quantity failed. I understand that the reason for such was that the crude product from which it was obtained was required in the manufacture of explosives. Various other products were tried, but were never of any particular value.

The arrangements for the bathing of troops and the disinfestation and laundering of their underclothing in the front areas, though not quite adequate, were generally most creditable, but there still remained the great problem of the disinfestation of outer garments. This was absolutely essential, as the infested khaki and cardigans were among the main sources of louse dissemination; in any routine, if it was to be successful, the salient fact could not be ignored that *all* the soldiers' clothing required repeated disinfestation at frequent intervals.

About the middle of 1915 and for a long period afterwards the usual establishment of disinfestation apparatus per division rarely exceeded one "Foden Thresh" and perhaps two horse-drawn "Threshes." These machines barely served to disinfest the underclothing alone, and a great deal of energy was also dissipated by their being used for blankets, which were minor sources of infestation. Occasionally local conditions were favourable, as at the well-known cloth factory at Nieppe, Armentières. Here, during the summer, autumn, and winter of 1915, one of the huge dye-vats, instead of being used as a bath, was converted into a successful steam disinfestor by the authorities of the 50th Division. Khaki clothing was thrown into it, the lid lowered, and steam turned on from the main pipe which heated the other vat baths. Such adaptations, however, of necessity were the exception in the front area. About this time, too, failing the provision of large appliances, attempts were made at divisional baths to disinfest the khaki by ironing. This method, which was abandoned by the summer of 1916, failed because of the disproportionate amount of space, labour, and expense involved.

Early in 1916, in connexion with their bath and laundry at Neuve Eglise, the Canadian Corps introduced steam disinfesting chambers for treating the outer clothing, and similar chambers were constructed later at Dranoutre and Westoutre. The chambers at Neuve Eglise were heated by steam generated by an old local threshing machine, but as the idea became more generally exploited vertical boilers were provided. Among the British corps this idea made slow headway, and there was an absence of standardisation of disinfestation methods as well as a lack of coördinated effort. This could be witnessed when divisions were "changing over," as time and again the new personnel from the incoming divisions, after taking over the established bath and disinfestor, allowed a successful routine to lapse owing to unfamiliarity with the idea of disinfestation, let alone with its operations.

At the beginning of 1917, at a laiterie near Poperinghe, a large steam plant of five chambers was erected as a corps disinfestor, the steam being supplied from the two large horizontal boilers of the adjacent laiterie. The main object of this large effort was the disinfestation of the outer clothing of troops attending the three corps baths in Poperinghe. In this scheme the clothing was returned to the troops after 24 hours, the men meantime being accommodated with special suits from the corps' stock. In addition, troops were brought to the laitèrie and all their clothing treated while they waited in bath gowns in marquees near by. Owing to an attack of trench fever and removal from that area I was never able to obtain figures to illustrate its beneficial effects upon troops which repeatedly used the institution.

Such efforts as these in the front areas undoubtedly did a great deal of good, but in a sporadic fashion, because three factors operated which prevented their being exploited to the full. These factors were (1) insufficiency of disinfestors, (2) consequent inability to give adequate repetition treatment to the same troops, and (3) as instanced above, lack of general understanding of the idea and methods of disinfestation.

It is a curious fact that in my experience the rest areas which, one would think, were the ideal places for the wholesale cleaning of troops were almost totally unprovided with plant, while the regimental routine did not provide for "resting" troops any opportunity for a thorough de-lousing and clean-up.

In May, 1917, I was recalled to England, and in collaboration with Captain J. Taylor Grant, R.A.M.C. (T.F.), was instructed to work at various aspects of disinfestation, the principal objects being (1) to ascertain the value of sulphur dioxide generated by the Clayton gas apparatus as a method of disinfestation, and (2) the devising of a portable apparatus for hot-air disinfestation. The results of the greater proportion of this work are incorporated in Professor Nuttall's "Combating Lousiness among Soldiers and Civilians."[3] About this time Captain Jacobs, R.A.M.C. (T.F.), and Major H. Orr, C.A.M.C., were working out their hot-air disinfestors in France, which resulted in both types being completed early in 1918.

Comparison of Types of Disinfestor.

Now in most of the appliances mentioned heretofore there is an obvious drawback; they are only of service in stationary warfare. My experience of the conditions in France and also of the experimentation carried on there and in England decided me (in common, I dare say, with others) that the exemplar of disinfestors for campaigning still remained to be evolved. The great qualification demanded of it is suitability for both stationary and mobile warfare, but before making suggestions on this point it would be well to summarise the qualifications of the most useful devices in use during the war. Full details of their value are quoted in Professor Nuttall's work.[3]

Apparatus.	*Advantages.*	*Disadvantages.*
Horse-drawn Thresh. Foden steam lorry Thresh.	Mobile; efficient.	Heavy; compared with Canadian steam disinfestors, uneconomical in working; unsuitable for leather articles;* somewhat expensive.
Steam Canadian disinfesting chambers.	Efficient; economical.	Stationary; unsuitable for leather.
Hot-air chambers—Jacobs or Orr types. Hot-air chambers—Orr-Grant type.	Efficient; economical; suitable for leather.	Stationary; the Orr and Orr-Grant types limited to one type of fuel—coke.
Canvas hot-air hut; Grant-Peacock type.	Mobile; cheap; readily erected.	*Limited to one type of fuel—coke.*

* Leather strappings on riding breeches are a nuisance in disinfestation. They are not really essential, and cloth strappings can be substituted.

Towards the end of 1917, if not before, I forwarded the suggestion that two suitable types of disinfestor could be constructed on the following simple lines:—

Type A, for transport on a horse-drawn wagon.—A large box, asbestos lined, about 5 ft. long, 3 ft. broad, and 4 ft. high, capable of holding 20 suits of three garments (tunic, trousers, and cardigan), or equivalent load in other garments, &c., modelled after the pattern of the Canadian huts; steam to be led from a small, strong, vertical boiler capable of generating it at 15 pounds pressure.

Type B, a steam-wagon disinfestor.—Two boxes as indicated in Type A, fitted on a steam lorry, steam to be obtained from the boiler of the lorry. These types would combine the good points of the Thresh machines and the Canadian steam chambers. They would have the mobility of the former with the additional advantages of being cheaper, lighter in weight, far more economical in steam, and capable of using coal, coke, or wood. I would suggest that the establishment of such be one of Type A per battalion, pro rata for other troops, while the larger type could be employed at baths, large hospitals, and concentration camps. They could be incorporated into any schemes of bathing and even, if necessary, their steam utilised for the heating of bathing water.

Steam-train disinfestors.—In view of the great success attending what has been called "Hunter's train" in the East, another idea suggests itself—why not use a lighter type for narrow gauge lines which tap country not accessible by larger plant? Of course, the type of mobile disinfestor employed would depend upon the nature of the country and campaign; obviously, for example, trains would be most suitable for desert warfare.

Conclusion.

This very brief account of the antilouse campaign at the Western front may be brought to a conclusion by reference to one of the most interesting and remarkable events in its history—in March, 1918, trench fever was proved a louse-borne disease. This provided a most convincing and stimulating argument for disinfestation, but the new spirit moved too late. The German offensive caused the destruction of much of our plant, while our counter-offensive and mobile warfare precluded the use of the surviving apparatus.

To those of us who endured lousiness and who worked on the experimental side of the problem the foregoing history brings melancholy reflections.

ACUTE PUERPERAL SALPINGO-PERITONITIS.*

BY ALECK W. BOURNE, M.B., B.CH. CANTAB.,
F.R.C.S. ENG.,

OBSTETRIC SURGEON TO QUEEN CHARLOTTE'S HOSPITAL; OBSTETRIC SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL, ETC.

A QUICK succession of cases presenting the same or similar conditions affords a special opportunity for study and comparison; hence I venture to bring forward a record of personal observations of a disease of which I have been fortunate enough to see and treat several examples during the last three years.

A word is necessary to explain the name I have adopted for a well-known condition. "Salpingitis" is not enough, while "salpingo-oöphoritis" is often wrong, especially early in the disease; but "salpingo-peritonitis" lays due emphasis on the essential peritoneal factor in the pathology and treatment. Further, I am chiefly concerned with acute salpingitis, occurring in a previously healthy tube, which appears to me to be more common than is generally supposed, and which gives rise to the characteristic clinical picture which I wish to describe.

If the condition is an exacerbation of previous tubo-ovarian disease such chronic changes must of necessity have been slight for pregnancy to have occurred, and any such exacerbation largely takes on the form of an acute suppurative salpingitis of recent origin. Acute puerperal salpingitis differs in so many aspects from that of non-puerperal origin, particularly as regards the physical signs and treatment, that it should be considered as a separate disease.

Anatomical Conditions in the Puerperal State.

The general physiological state, together perhaps with an altered resistance to infection, are important factors distinguishing the puerperal from the non-puerperal woman, but the fundamental difference which is responsible for its individual consideration is anatomical; it lies in the peculiar anatomical conditions of the abdomino-pelvic organs during the first fortnight after labour. The tubes are essentially abdominal, not pelvic, organs; and they are usually affected before they have reached their normal positions in the pelvic cavity. By the end of the first week, when symptoms generally manifest themselves, the tubes lie at or just above the pelvic brim, in relation with the iliac vessels; while the ovaries are placed below, just within the pelvis, and applied to its lateral walls. The former are, therefore, outside the limitation of the pelvic basin, and are surrounded by coils of small intestine, which considerably alters the results following escape of pus from the abdominal ostia, as compared with a similar tubal condition where the tubes are lodged within the pelvic cavity. In the latter case, as is well known, the resulting abscesses are strictly circumscribed in the pouch of Douglas, and the whole inflammatory area tends to be roofed in and delimited by the omentum or small intestine. General extension of the infection into the abdominal peritoneum is unusual, and the symptoms and signs are correspondingly localised. Resolution is a frequent result; the patient recovers without operation, and may regain a fair state of health. But in puerperal salpingitis conditions are different. The abdominal situation of the tubes is the cause of an abdominal as opposed to a pelvic peritonitis, inasmuch as it allows the outpouring of pus amongst the coils of small intestine at or just above the level of the sacro-iliac joint; herein lies the essential difference between the two varieties of salpingitis, a difference which is manifest as much in the physical signs exhibited as in the treatment required. Further, the hyperæmic condition of the uterus and appendages during the puerperium will also have its share in modifying the gravity of the symptoms and the rapidity of their course.

---

* A paper read before the Section of Obstetrics of the Royal Society of Medicine, on March 3rd, 1921.

The involution of the uterus appears to be arrested in all these cases at a point at which the fundus extends about half-way between the symphysis and the umbilicus. This may be due to the presence of infection within its cavity or possibly to a neighbouring active suppuration in the tubes, but the important result is that the tubes are maintained at their high level at or above the brim of the pelvis for a considerable time after the inception of the disease. Moreover, the large uterus nearly fills the pelvic cavity, and affords a fixed point comparatively high up in the abdomen proper for the development of adhesions with other parts.

Morbid Anatomy in the Acute Stage.

The morbid anatomy is well seen when operation is undertaken in the acute stage. The tubes are seen to be greatly congested and œdematous, especially in the ampullary portion, while the fimbriæ are protruding and the ostium is discharging pus. The isthmus may appear to be quite normal or swollen to a less extent. Any adhesions at first are light and easily separated, often being due to flakes of recent lymph and chiefly involving adjacent coils of small intestine and part of the cæcum or pelvic colon. The abdominal ostium frequently opens into a small abscess cavity walled in by the adherent coils and situated at first just in front of and above the sacro-iliac joint. Later, when suppuration has extended, it tends to pass forward along the brim of the pelvis towards the uterine cornu and is shut in from above by the omentum, or the pus may even come into relation with the abdominal wall, and I have seen eruption of the abscess through the parietal peritoneum into the layer of fat beneath the rectus.

The Course of Puerperal Salpingitis.

It is noteworthy that the pouch of Douglas early becomes obliterated in nearly every case by a light adhesion of its anterior and posterior walls, extending to the depths of the fossa, and effectually preventing the formation of a deep abscess. This is a point of considerable importance both as regards the physical signs and the technique of the operation, for it is in sharp contra-distinction to the state of affairs which exists in ordinary non-puerperal salpingitis, where inflammatory collections appear at the lowest part of the pouch. In puerperal salpingo-peritonitis invasion of the pouch of Douglas is secondary to the extension of pus from the primary focus at the ostium of the tube as it burrows from above downwards along the postero-lateral wall of the pelvis. It is only at the delayed operations that the fossa is found to contain an abscess, and then not in its depth, but spreading from the infected ovary. Similarly the utero-vesical pouch may be effaced in whole or part by adhesion of the bladder to the anterior uterine wall.

A secondary condition sometimes found in cases operated on at a later date is a cellulitis of the upper part of the broad ligament which has spread forward from the meso-salpinx to involve the tissue beneath the round ligament. Under these circumstances the upper part of the broad ligament becomes an indurated dome-shaped mass limited behind by the tube, and in front by the round ligament, presenting an upper triangular surface having its apex at the uterine cornu. Later, the infection affects the cellular tissue in front of the round ligament, which then takes up a position riding over the convex surface of the cellulitis. It is common also for the inflammatory process to extend over the pelvic brim into the iliac fossa, and also along the infundibulo-pelvic ligament as in ordinary parametritis. A mild degree of œdema is common in the meso-salpinx in the earliest cases, but it may be the forerunner of an extending cellulitis, as I have stated. When suppuration occurs here it tends to point just external to the uterine cornu in the angle between the round ligament and the tube. It is this which sometimes accounts for the firm adhesion of the uterine cornu to the omentum or abdominal wall, and furnishing an important physical sign in the shape of a localised point of exquisite tenderness just external to the lateral edge of the uterus.

Suppuration of the ovary can arise in three ways. Firstly, it may be a late result of acute purulent salpingitis after adhesion with it has occurred, as is commonly seen in the gonococcal cases; secondly, it may be an exacerbation of an old condition of salpingo-oöphoritis; and thirdly, from the wall of the gut by direct extension. This is the only explanation I can give of a case I recently operated upon. The tubes in this patient were perfectly normal, lying just above the pelvic brim, but the left ovary, which was not the subject of old inflammation or adhesions, was fixed by its convex border to the pelvic colon, which at this point was indurated and œdematous. On separating the two a small collection of about half a drachm of pus was liberated. Evidence of the gut as a direct channel of infection is also supplied by another case of suppurative salpingo-peritonitis where *Bacillus coli* was grown only from the peritoneal abscess and not from the tube or uterus, which yielded streptococcus and gonococcus respectively. The spread of pus infection to the normal ovaries is a serious matter, as, short of removing the organ, it is difficult to eradicate when once established. Moreover, in these cases ovarian infection is the starting point of a descending suppuration. The first mass that can be felt by vaginal or rectal examination is the infected ovary surrounded by adherent coils or omentum. From this initial peri-ovarian abscess pus spreads downwards to form a collection in the pararectal fossa. Later the ovary can be felt as an enlarged mass, a fact due to its containing an intra-ovarian abscess.

The subsequent morbid anatomical changes can be studied during the delayed operations. Then it is seen that the chief change has been the formation of dense adhesions involving all the pelvic organs, together with the omentum and intestine. Especially are the tubes and ovaries firmly bound down to the large uterus and pelvic brim. Suppuration tracks in all directions, causing large peritoneal abscesses, and the ovary may be converted into a large pus sac. General suppurative peritonitis appears to be rare as the result of purulent salpingitis, though we know that it is not uncommon in trauma of the uterus in labour or abortion, and it is sometimes seen in septicæmia.

The bacteriological examinations of my cases have been too few to justify any conclusion, but four cases have all grown streptococci, with gonococci once, and *Bacillus coli* also.

Cause of the Disease.

We know that the disease is due either to extension of organisms along the tube from the infected uterus or to an exacerbation of previous salpingo-oöphoritis, which must of necessity have been only slight in degree or unilateral. That the former does frequently occur is certain, and can be easily understood; but I believe that the disease is sometimes caused by organisms that have lain dormant for a long time in otherwise perfectly normal tubes, and the following case proves this.

Some two years ago a patient, at the commencement of labour, underwent a deliberate Cæsarean hysterectomy by Mr. C. W. G. Bryan at St. Mary's Hospital. The tubes were divided and ligatured in the ordinary way at the uterine cornua. The convalescence was normal and undisturbed till the end of a week, when she developed signs of acute lower abdomen illness. We reopened the abdomen together, and found both tubes in a state of acute purulent salpingitis, leaking pus into the usual peritoneal abscess cavities situated around the abdominal ostia. The tubes showed absolutely no trace of old adhesions, and the fimbriæ were separate and protruding around the ostium as a result of œdema. Moreover, Mr. Bryan assured me that there was at the first operation no sign of old salpingo-oöphoritis.

This case proves conclusively that the disease can arise entirely independently of post-partum uterine infection, for here there was no uterus at all, and also that potentially dangerous microbes can lie quiescent in an apparently normal tube. Incidentally I might add that I believe the tube can exercise an inhibitory effect on microbes within its lumen at ordinary times, for I have succeeded, for instance, in growing streptococci from the peritoneal abscess cavity around the tube and from the uterus, but have failed to cultivate a microbe from the pus within the tube in the same patient. But during the puerperium this defensive mechanism—if there be any, in fact—appears to deteriorate and allow an outburst of organic growth previously held in check.

Symptoms and Signs.

There is little noteworthy about the symptoms, for they are those commonly complained of in an acute lower abdominal peritonitis. A few points, however, may be emphasised. As in acute appendicitis, pain precedes everything and is rapidly followed by a slow rise of temperature to reach 102° or 103° F. on the third or fourth day, with a pulse following suit. Vomiting is not a feature in the early cases. An interesting and indicative symptom occasionally is retention of urine or painful micturition, and is specially seen in cases where a cellulitis has developed secondarily to the salpingitis involving the upper part of the broad ligament and extending forward beneath the round ligament to the neighbourhood of the bladder. If the patient is not operated upon there is a persistent fever, with chronic pain and wasting; she slowly goes down hill, develops cardiac weakness, and is bedridden.

The physical signs require more detailed description.

In the early stages the abdomen is not truly rigid and there is nothing but tenderness fairly accurately localised to a point about 2 inches below and external to the umbilicus—i.e., over the posterior part of the lateral brim of the pelvis. The fundus uteri can be felt rising about 2 inches above the symphysis. It may or may not be tender at first, but later becomes so, especially if adhesions become attached to the cornua or if a secondary cellulitis develops. After a week or more it is not unusual to find a mass in the hypogastrium to one side of the fundus uteri. Excepting cellulitis, which is felt immediately above Poupart's ligament, such a tumour is nearly always due to adherent omentum and coils of distended gut. Later as suppuration spreads there is true rigidity and tenderness of the whole hypogastrium, with extension upwards over the ovarian veins, if thrombosis of these vessels has taken place.

Per vaginam the signs are difficult to appreciate, for the primary changes are not in the pelvis, and the gentlest manipulation causes pain. The uterus can be felt enlarged, with limited mobility soon developing, and later complete fixity. In the first few days it is symmetrically disposed in the pelvis, but later it may be displaced laterally by secondary cellulitis, and the displacement is towards the side affected. During the first week there may be little or nothing felt in the lateral fornices, but later an indefinite tender mass can be felt very high up in the postero-lateral region, which is largely made up of the ovary surrounded by adherent coils enclosing pus. The accessible part of Douglas's pouch seldom, if ever, contains anything, though per vaginam the posterior portion of the lower part of the uterine body may give the impression of a tumour, because it tends to bulge backwards immediately above the cervix. By far the best palpation of the pelvis is gained by rectal examination. High up on one or both sides the early composite swelling can be made out fairly early, becoming larger and more distinct as time passes.

A swelling high up in the broad ligament disturbing the position of the uterus is probably a mass of secondary cellulitis.

Treatment.

The treatment of this disease is, perhaps, the most interesting part of its discussion. Whether or not operation should be done is a question less contentious than *when* it should be done. In the great majority of these patients there is no doubt that operation is necessary, for the condition is essentially one of suppurative peritonitis, which, unless relieved, will show no tendency to undergo spontaneous resolution. The condition is totally different, as we have seen, from the ordinary acute gonococcal salpingo-oöphoritis where the whole process is confined within the limits of Douglas's pouch, and where also experience has shown that almost complete resolution is possible in the majority of cases. Moreover, the peccant organism in puerperal salpingitis is frequently a streptococcus, which the peritoneum is far less able to tolerate and suppress than the gonococcus. Further reasons are that the tubes being subinvoluted, soft and distensible, are more liable to develop into pus sacs, while the involution of the uterus is permanently delayed, probably laying the foundation of a chronic hypertrophy. But the time at which operation should be performed is the point which admits of difference of opinion.

My own view is that puerperal salpingo-peritonitis should be operated upon as early as the diagnosis is established, for the following reasons:—

1. If radical treatment is delayed the general condition of the patient rapidly deteriorates. There is loss of flesh and strength, amounting later to emaciation, with the danger of cardiac failure following an operation performed as a last resort.
2. The ovaries, which are at first free from suppuration, are prone to develop small abscesses, and later become disorganised. When once the ovary has become the seat of a pus infection it is extremely difficult to eradicate it without removing the whole organ; and if such an ovary is left in situ it forms a source of chronic pelvic trouble.
3. The adhesions become tougher with delay and more difficult to separate, involving risk to the gut, more extensive raw areas, and more time to complete the operation. Strong adhesions form a serious additional risk to the operation.
4. The tubes become thoroughly disorganised and incapable of repair. The delicate ciliated epithelium is desquamated, granulated tissue takes its place, and the walls become permanently thickened. The tube as a whole becomes densely adherent to the ovary, the uterus, and lateral wall of the pelvis. Removal of such a tube may be an almost impossible task without injury to the gut or even to the ureter, and yet if these appendages are left in situ the patient's convalescence may drag on for months or even a year with a chronic sinus and emaciation.
5. The peritoneal abscesses extend and may reach the abdominal wall, especially over the uterine cornua. In one patient the pus had actually tracked through the peritoneum and had formed an abscess in the paniculus beneath the rectus.
6. Secondary cellulitis of the upper part of the broad ligament may develop if the condition is not relieved by operation. This sometimes goes on to pus formation pointing at the cornual angle. Cellulitis is a serious extra burden for the patient, delaying the convalescence, adding fresh possibilities because of its dangerous lines of extension, tending to produce thrombosis of the ovarian veins, and liable to leave a legacy of chronic pelvic pain.

Almost any one of these reasons is sufficient, but taken together they certainly make a good case for early operation. The disease is quite different from acute gonococcal salpingitis, and the objections to early operations in this condition do not here obtain.

Operation.

The operation itself should be done with great care, and sound judgment is necessary to determine the exact procedure required by each individual case.

After the abdomen is opened and the cut edges of the peritoneum clipped to towels, the upper part of its cavity must be thoroughly packed off by gauze in the usual way. Obstructing adhesions are then separated, and the region of the abdominal ostia of the tubes is sought, as it is here that a peritoneal abscess will most likely be found. Great care should be taken not to disturb the light adhesion which has probably obliterated the pouch of Douglas and possibly also the utero-vesical pouch. The tubes and ovaries are inspected to note particularly whether the affection is entirely recent or whether there is evidence of old inflammatory trouble. In the former case the ostium will still be patent, surrounded by œdematous fimbriæ, and if the tube be gently squeezed pus will exude from its open end.

Now such a tube is a potential pus sac, but at the same time it still possesses a mucous membrane capable of restoration to a functioning condition, provided that operation is undertaken during the first few days; this point can easily be demonstrated microscopically. Therefore to leave the tube alone is to invite chronic inflammatory changes, perhaps a pyosalpinx, with a train of chronic pelvic symptoms; whereas removal of the tube at this stage is too radical a measure for an organ which is capable of complete restoration. The correct surgical treatment, I believe, lies in permanently laying open the tube in order to drain it. Scissors should be entered at the ostium and the ampulla opened up. This procedure is exactly comparable to the laying open of an ill-draining abscess cavity with the object of terminating the suppuration and preventing further damage by the continuance of a subacute inflammation set up by the presence of pus under a certain degree of tension. The ostium, while it remains patent, is incapable of affording free drainage of tubal contents, and soon, as we know, in septic infections the fimbriæ adhere and close the opening. Salpingostomy immediately destroys the tube as an abscess cavity, but does not destroy it in its capacity as a future ovum-bearing channel, provided that it is done at an early stage of the disease. Further, by checking the suppurative and inflammatory processes within the tube not only is a pyosalpinx impossible, but there is no longer a tendency for the formation of chronic interstitial salpingitis with permanent closure of the ostium and complete destruction of the ciliated epithelium.

That an acutely suppurating tube can undergo complete resolution after salpingostomy I have recently had occasion to witness.

A patient at the Willesden Municipal Hospital in whom I carried out this operation on the left side developed pneumonia and died about a month after. At the autopsy I found that this tube had completely resolved. It had shrunk to the normal size and its gutter was lying open, while it had contracted absolutely no adhesions. This was in spite of a small chronic abscess holding about half a drachm of pus between the ovary and lower part of broad ligament.

I was much impressed by this case, as originally the tube was in a condition of acute suppurative salpingitis, from which streptococci were cultivated. If, however, the tubes and ovary show signs of former inflammation and are bound down, giving no promise of ever being able to function again, they should be removed in the ordinary way. Otherwise they are liable to furnish chronic foci of suppuration and the patient's convalescence is immensely prolonged. The delayed operation—i.e., performed after two or three weeks, may be difficult and dangerous on account of the appendages being enveloped in very dense adhesions. There is now little hope of saving the tubes; in fact, it is usually necessary to remove them to ensure a reasonably quick recovery. Mere drainage of the peritoneal abscess cavity is not sufficient. Secondary cellulitis of the upper part of the broad ligament should be incised radially from the cornu between the round ligament and the tube and explored by a sinus forceps. Pus is frequently found, but if not the escape of serum and œdematous fluid materially hastens subsidence. Before closing the abdomen the suppurating areas should be drained.

Conclusions.

The general principles, therefore, in operating on acute puerperal salpingo-peritonitis are to employ conservative measures on structures in an acute condition in order, firstly, to save them, and secondly, to prevent chronic changes developing in them, but to deal radically with acutely inflamed and seriously damaged appendages in spite of dense adhesions which may be present. In this way much can be done to conserve function, to prevent chronic disease, and to provide for reasonably quick recovery to normal health.

A FURTHER SERIES OF FORTY CASES OF BONE-GRAFTED MANDIBLES.

BY GILBERT CHUBB, D.Sc., M.B. LOND.,
F.R.C.S. ENG.,

SURGEON TO THE THROAT HOSPITAL, GOLDEN-SQUARE; AND PLASTIC SURGEON TO THE QUEEN'S HOSPITAL FOR FACIAL INJURIES, SIDCUP.[1]

SINCE the publication of my earlier paper[2] I have bone-grafted 40 additional patients, bringing the total series up to 100. In the first 60 cases, a complete analysis of which I have already given, bony union was obtained in 93 per cent. In the 40 subsequent cases bony union has been so far obtained in 24, 4 are definite failures, and the remainder, nearly all quite recent cases, appear to be consolidating satisfactorily.

The operative technique has remained unchanged; the graft in every case has been taken from the crest of the ilium, fitted and securely wired into accurate end-to-end apposition with the jaw fragments by means of the "templates" described in my earlier paper. In practically every case the whole depth of the jaw has been utilised in the formation of the facet for apposition with the graft. In the case of the posterior fragment this facet has frequently measured from 1 inch to 1½ inches in vertical extent. (Fig. 1.) The graft has been fashioned of a like depth. The result is a solid reconstruction of the mandible devoid of all trace of spring, and with an "alveolar border" continuous with that of the jaw fragments. This upper or alveolar border of the graft is at first formed by the open cancellous tissue of the iliac crest. Successive observations with X rays, however, show that with exposure to the stresses incidental to the use of the jaw, this upper border becomes rounded off with a layer of compact bone.[3] Clinically it has been observed that the upper border of the graft becomes capable of bearing the direct pressure of a denture within a few months of the operation. In three cases it was possible to verify this condition of the graft, in two cases during life and in one after death.

As foreshadowed in my earlier paper, the practice has been adopted as a routine of opening the splints and allowing free use of the mandible at the second or third week after operation. In nearly all the cases the loss of bone extended beyond the standing teeth, so that this practice resulted in exposing the grafted mandible to considerable strain. The results have confirmed my earlier impression that this exposure hastened consolidation of the union. Radiograms show distinct evidence of union in the form of delicate striæ across the line of junction at the third or fourth week. By the third or fourth month radiograms, as a rule, show no trace of the line of union. This rapidity of union is entirely independent of the size of the graft. Cases 68, 71, 72, and 79 (Fig. 2) were all cases in which the loss of bone extended from the canine region well into the ascending ramus, and all showed clinical union with no trace of spring by the fourth week after operation. Three of these cases had had a bone graft which had failed to unite prior to coming under my care.

In my earlier cases I frequently split the graft, using only half its thickness, the deeper aspect of the graft consisting of open cancellous tissue, and only one layer of compact bone being present. The more complete exposure of the jaw fragments in later cases has enabled me to accommodate the entire thickness of the graft, but that the earlier practice in no way interferes either with the survival of the graft or with its rapid union with the jaw fragments is shown by the fact that Case 68 quoted above is one of the few instances in which this practice has been followed among the more recent cases. Opportunities occurred for examination of the nature of the union obtained in three cases respectively 6, 15, and 18 months after the bone-grafting operation.[4] The specimen at 15 months was obtained owing to the necessity for resecting the posterior union in order to open the mouth, the posterior fragment being so fixed by fibrous tissue as to resist less drastic treatment. The case at 18 months was a post-mortem specimen. Sections from both cases were ground on the finger. When sufficiently thin for mounting they could not be bent at the zone of union. They were stained with mallory, which has an especial affinity for fibrous tissue. The periosteal tissue on the surface of the sections is deeply stained, while the zone of union in each case remains unstained. (Fig. 3.) When viewed under the higher power of the microscope this region is seen to consist of dense bone, the lamellæ and lacunæ of which are distinctly visible. (Fig. 3A.)

[1] A résumé of a paper read to the Surgical Section of the Royal Society of Medicine, February, 1921, when cases, radiograms, and microscopical sections were shown.

[2] THE LANCET, 1920, ii., 9.

[3] A similar architectural adaptation of stress has been described for the tibial graft in Albee's operation for Pott's disease.

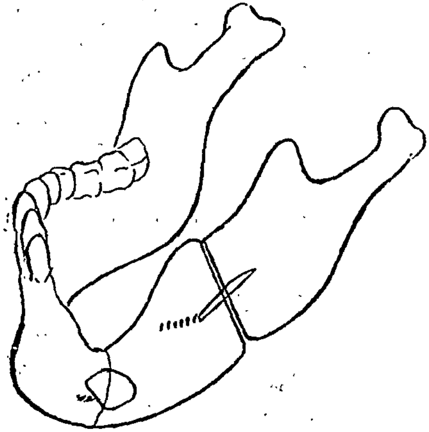

FIG. 1.—Diagram taken from an X ray five weeks after operation. Four months later all trace of the line of union had disappeared.

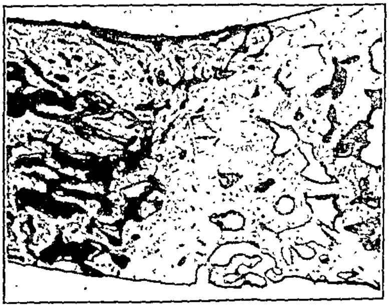

FIG. 3 (Case 40).—Ground section of bone across union of graft and posterior jaw fragment 18 months after the bone-grafting operation. The deeply-stained periosteal tissue is sharply contrasted with the absence of fibrous tissue in the zone of union. (The demarcated area A appears enlarged below.)

I did not commence bone-grafting for the repair of the fractured mandible until the end of 1918. To this circumstance is, perhaps, due the very large proportion of the cases—well over 80 per cent.—in which the loss of bone extended beyond the standing teeth, or even involved the ascending ramus. To the same cause is due the considerable number of cases in which one, or even two, bone-grafts had been inserted and had failed to unite prior to the patient coming under my care. In only one of these cases have I failed to obtain bony union. In this case there had been two previous bone-grafts; the loss extended from the canine region almost to the condyle, and the graft I inserted was fully 4 inches long. Infection followed the operation and the graft was subsequently removed.

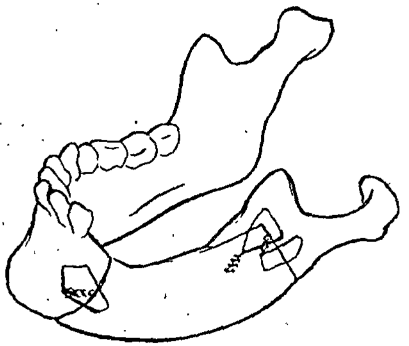

FIG. 2.—Diagrammatic representation of mandible of a Chinaman, who proved a very unruly patient. He removed his stitches with a razor a few days after operation, and soon afterwards removed his splints; nevertheless his graft was quite firm after the fourth week. He has since returned to China. This was one of the cases referred to in which a previous bone-graft had failed.

Nothing has contributed more to the great progress reconstructional oral surgery has made during the last few years than the intimate coöperation which has been established between the operating and the dental surgeon. All the cases have been operated upon at the Queen's Hospital for Facial Injuries, Sidcup. Throughout the work I have had the advantage of the expert advice and encouragement of Sir Frank Colyer, the consulting dental surgeon to the hospital. For the great majority of the cases the dental and prosthetic treatment has been carried out by Mr. B. Mendleson, to whose active and whole-hearted coöperation I stand much indebted. The sections showing the nature of the union obtained have been very kindly made for me by Mr. James T. Carter.

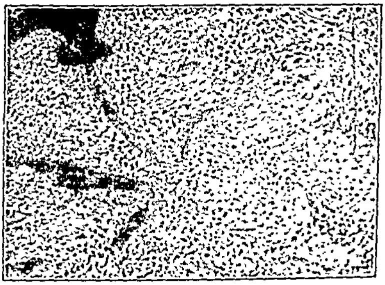

FIG. 3A.—The demarcated area in Fig. 3, shown at a higher magnification; the lamellæ and lacunæ of the dense bone are clearly seen.

---

[4] The section at six months was from a decalcified specimen, and was described in my previous paper.

◆

TWO CASES OF GANGRENE OF THE LUNG

COMPLICATING INFLUENZAL PNEUMONIA.

BY J. DE VILLE MATHER, M.D. MANCH.,
ASSISTANT PHYSICIAN, MANCHESTER NORTHERN HOSPITAL;
AND
F. B. SMITH, B.CH. CANTAB.

THE account by Dr. Cronin Lowe in THE LANCET of Jan. 15th of three cases of severe colitis found post mortem after influenza recalled the following two cases of gangrene of the lung seen by us during the same influenza epidemic. In view of the similarity of one form of this disease to a true septicæmia such a complication might be expected to result from an embolus. At the time—i.e., June, 1918–March, 1919—no instance of pulmonary embolus recorded by others came to our notice, and during the two years subsequently a search through a considerable portion of the literature has failed to show any reference to the condition. The reason for recording the cases is not that we think them very unusual, but in order to ensure that the picture of the disease may be made as complete as possible. One case was diagnosed before death; both were fatal.

CASE 1.—Lieutenant ——, aged 23. Admitted Oct. 21st, 1918, from transport ship after reporting sick six days previously. Irritable dry cough. Temp. 101·4° F. Headache, sore throat; copious, blood-stained purulent sputum for last 24 hours. Poor air entry over whole of chest, with small localised area of broncho-pneumonia in the left lower lobe. 23rd: Pyrexia subsided by lysis; P. 60, R. 20, chest remarkably clear of signs; patient merely exhausted. 27th: Allowed to sit up in easy chair. 29th: While sitting up in chair at 6 P.M. sudden acute attack of pain in the left lumbar region. The patient likened this pain to lumbago; its sharp stabbing onset was very noticeable. No physical signs obtained. Chest still clear. 30th: T. 100, P. 90, R. 26. Examination of chest, abdomen, and urine negative. No cough; patient could lie only on the right side; abdominal muscles quite rigid. 31st: Hæmoptysis of about 20 oz. of dark blood, with striking relief of pain in the side; diagnosis of pulmonary embolus made. Nov. 2nd: Sputum copious, muddy, limpid, no mucus, very offensive; small effusion of fluid left base; sputum showed no pus cells, appeared to be a pure culture of a diplo-streptococcus. 8th: Left chest explored, fluid withdrawn having the same characteristics as the sputum.

Operation.—This lasted half an hour under chloroform and ether. A portion of the seventh rib was excised; incision opened directly into a large gangrenous cavity in the deep substance of the lower lobe of the lung, apparently well shut off from the upper pleural cavity. T. subnormal, P. 100, R. 28. Wide drainage. 12th: Gaseous cellulitis of chest and loin; extensive incisions. Carrel-Dakin's tubes. Impossible to apply local antiseptics to the chest cavity on account of threatened asphyxiation of the patient by any fluid introduced. 18th: Extension of the cellulitis to the buttocks; lobar pneumonia right lower lobe with clear pleural effusion. 21st: Death.

Post-mortem findings.—Heart: Excessive clear fluid in the pericardium. Right ventricle completely filled by organised ante-mortem clot extending continuously through the pulmonary valve along the artery beyond its first bifurcation. Right lung: 10 oz. turbid pleural effusion. Dense fibrinous pleural membrane. Lower lobe shows massive consolidation commencing to resolve. Left lung: Upper half of the upper lobe normal. The rest of the lung wholly destroyed by a stinking, gangrenous cavity with bronchioles, arteries, and connective tissue strands necrosed, and bridging the cavity, which is firmly shut off by adherent pleura from the upper half of the pleural sac. The upper division of the artery to the upper lobe is patent, lower division completely occluded by an extension of the organised clot from the heart, a quarter of an inch in diameter. Artery to the lower lobe completely occluded by an extension of the organised clot from the heart, its termination visible in the wall of the cavity, and half an inch in diameter.

CASE 2.—A sergeant, aged 23. Admitted on Oct. 3rd, 1918, off transport ship third day after reporting sick. Well-marked broncho-pneumonia left lower lobe. 8th: Pyrexia gone by lysis. 14th: Pleural effusion left side. 15th: Thin pus withdrawn; excision of part of seventh rib; wide tube drainage. 18th: Discharge ceased; later in the day a sudden attack of pain in the left side, with discharge of serous limpid fluid through the drainage-tube. 19th: Fluid draining from the chest in a surprisingly large amount; pyrexia high; general condition worse. 25th: Heart failing; high "septic" fever; profuse sweating for last six days; loud amphoric respiratory murmur over whole of left chest. 27th: Death.

Post-mortem findings.—Right lung normal. Left lung upper lobe apsed. Pleural membrane thick and fibrinous, with some localised pockets of pus adjacent to the pericardium and on the left surface of anterior mediastinum. Lower lobe, gangrenous stinking cavity 3 by 2 inches in dimensions, bounded below by the diaphragm and involving one-third of the mass of the lobe. The rest of the lobe shows resolving massive consolidation. Embolus or thrombus to account for the gangrene could not be found. Heart: Apparently normal; no ante-mortem clot.

Remarks:

It may be that Case 2 was an abscess of the lung of other primary origin than an embolus, but the type of lesion post mortem certainly suggested embolic origin in spite of the fact that an occluded artery could not be demonstrated. These two cases occurred amongst a series of 49 other post-mortem examinations made during the course of the epidemic. In two other of these cases there were present small multiple abscesses, not gangrenous in type. In the comprehensive account of the disease and its pathology given by Drs. A. Abrahams, N. Hallows, and H. French in THE LANCET of Jan. 4th, 1919, no mention is made of pulmonary embolism.

A NOTE ON

SPLENECTOMY FOR TORSION OF THE SPLEEN IN A CHILD.

BY A. H. SOUTHAM, M.A., M.CH.OXON., F.R.C.S.ENG.,
RESIDENT SURGICAL OFFICER, MANCHESTER ROYAL INFIRMARY.

TORSION of a wandering spleen in a child, followed by the operation of splenectomy, is a condition not often met with. The successful result makes the following notes worthy of publication.

J. H., a boy, aged 6 years, was brought to the Manchester Royal Infirmary on Dec. 31st, 1920, with a diagnosis of acute appendicitis. His mother stated that he had been seized with sudden abdominal pain the previous evening at 10.30 P.M. whilst he was in bed, and had been vomiting continuously ever since. He had never complained of abdominal pain previously. On examination he was found to have a temperature of 100° F., and a pulse of 120. The whole abdomen was held very rigid, with tenderness and rigidity most marked over McBurney's point. I decided to perform laparotomy immediately. When under the anæsthetic, a large and freely movable tumour was palpable in the right iliac fossa. The abdomen was opened through the right rectus muscle and the tumour was found to be an enlarged and congested spleen. The organ was without difficulty delivered through the incision, and the pedicle was then seen to be twisted on itself two and a half times. The pedicle was transfixed and ligatured in two halves, a second ligature encircling the whole pedicle. The pedicle was then divided, distal to the ligatures, and the spleen removed. The abdominal incision was sutured in layers. Convalescence was uneventful, and the child was discharged from hospital on Jan. 19th, 1921. The spleen was found to weigh 14 oz.—three to four times the usual weight of the organ at this age.

A blood film, taken immediately after the operation was completed, showed a slight polymorphonuclear leucocytosis, but otherwise no change from the normal. A second film, taken the day before his discharge from hospital, showed a leucocytosis with some diminution of the colour index. Microscopical examination of a section of the spleen showed extreme congestion of the organ; no other pathological changes were to be found.

The cause of the enlargement of the spleen is difficult to determine. The child showed no evidence of rickets or congenital syphilis, and the other abdominal organs appeared at the operation to be normal in size and position. The condition may have been congenital in origin or it may have arisen as a gradual process, slight torsion of the pedicle causing congestion of the organ and a slow increase in size, a sudden extra twist giving rise to the acute symptoms. There was, however, a complete absence of history of previous attacks of abdominal pain. It is interesting to note that the number of twists of the pedicle was the same as the average number of twists found in cases of torsion of an ovarian cyst or of the testis. The ectopic spleen is said to be usually found on the left side of the abdominal cavity; in this case it was well to the right of the median line. This position, the acuteness of the onset, and the marked tenderness and rigidity in the right iliac fossa made the condition closely simulate an attack of acute appendicitis. It would appear that the spleen can be removed in a child without any immediate ill-effects.

I am indebted to Mr. Charles Roberts, under whose care the patient was admitted, for permission to publish these notes.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

GENERAL MEETING.

ERADICATION OF TUBERCULOSIS IN MAN AND ANIMALS.

A GENERAL meeting of the Fellows of this society was held on March 14th, Sir JOHN BLAND-SUTTON, the President of the society, being in the chair, when a discussion of the eradication of tuberculosis in man and animals was opened by Sir JOHN MCFADYEAN, Principal of the Royal Veterinary College.

Prevalence of Bovine Tuberculosis.

He pointed out that, though there was a considerable number of diseases which were recognised as common to man and animals, yet in most of them cases of actual transmission from animals to man in this country were extremely rare, and transmission in the opposite direction was still rarer. Tuberculosis was the great exception to the rule among diseases of animals communicable to man. What was termed tuberculosis was met with in all the domesticated animals, but avian tuberculosis was now regarded as a disease distinct from that which prevailed in man and other mammals, and cases of its transmission to other farm animals or to human beings were unimportant on account of their rarity. For the veterinary profession the chief form of tuberculosis was that which affected the bovine species, and as regards economic importance it alone was important. It was essentially a disease of cattle in the sense that the type of bacillus which caused it would cease to exist if the bovine species became extinct. It was an independent disease of cattle in the sense that the eradication of human tuberculosis would leave its incidence among cattle unaffected. On the other hand, the eradication of bovine tuberculosis would reduce to nearly vanishing point the loss which tuberculosis at present caused in pigs and other farm mammals, and it would sensibly diminish the cases of human tuberculosis, especially those which had their starting-point in connexion with the alimentary tract.

Incentives to Eradication.

There were two incentives to an effort to eradicate tuberculosis from the bovine species; the one might be termed economic and the other humanitarian. In order to estimate the force of the *economic incentive* one must be informed regarding the loss at present inflicted by the disease on agriculturists and others who breed and keep cattle. Cattle of all ages were subject to infection with tuberculosis, and the incidence rose with the age and reached its maximum among old cows. It was scarcely possible to say what proportion of the entire cattle population was affected, because we had neither slaughter-house statistics nor the record of tuberculin-testing of young cattle on a sufficient scale to warrant precise conclusions. It was quite certain, however, that the proportion affected under 2 years old throughout the country was generally low. In breeding animals from 3 years upwards it could not be estimated at less than 30 per cent., and in the principal milking breeds it was probably at the present moment nearer 40 per cent. Much higher percentages were not at all rare in particular herds. In spite of this the mortality was low, and in well-managed herds it was often under 1 per cent. per annum over a period of years. Unlike some other contagious diseases of cattle, tuberculosis was thus not generally so serious from the farmer's point of view that he felt compelled to take measures to eradicate it from his herd if these measures involved either great trouble or great expense. There were exceptions to the rule that the existence of tuberculosis in a herd did not cause great loss, but in such exceptional cases one usually found that the owner had taken no precautions whatever, and that he had been in the habit of keeping tuberculous animals in the herd long after they had become visibly affected. In such circumstances not only was the proportion of animals affected increased, but the proportion of cases which assumed the clinical form and developed udder lesions was also increased. In cattle, as in man, in the great majority of cases actual infection did not become manifested by obvious deterioration of health.

With regard to the *humanitarian motive*, at the present time instructed medical opinion throughout the world appeared to be solidly in favour of the view that the frequency with which tuberculosis was transmitted from cattle to man provided a strong incentive to complete eradication of the bovine disease. He would be interested to hear what those present thought of the new view that the passage of tubercle bacilli from cows' udders to the stomach of children might actually be beneficial to the human species by producing an immunising effect and thereby diminishing the result of subsequent infection with the more virulent human type of the bacillus.

There was not the least doubt that the disease could be eradicated within a few years if that were considered necessary regardless of cost. This could be effected by enforcing the general testing of all cattle in the country, followed by compulsory slaughter of all reacting animals. Having regard to the facts already mentioned concerning the present incidence of the disease such a scheme was unthinkable. It would involve the slaughter of one-third to one-half of all the milking cattle in this country, and also a considerable proportion of the younger stock. Putting aside the fact that it would involve the payment of a huge sum of money to compensate for the slaughter of apparently healthy cattle it would greatly reduce the supply of milk immediately and for a good many years to come, and add in a proportional degree to its already high price. Concerning the question whether the ultimate complete extinction of the disease might not be achieved by some slower and less expensive method, he thought that, having regard only to the present stage of knowledge, the answer must be that unless a great discovery was made with regard to vaccination against the disease one could not hope for anything beyond a very slow reduction in its present prevalence. In such circumstances one might consider whether it would be useful to encourage in some way the voluntary efforts of owners to get rid of the disease. The eradication of tuberculosis from a herd, however, in this country was not practicable for more than an insignificant minority of farmers and others who kept milking herds. Those who owned valuable pedigree herds might succeed in freeing their herds from tuberculosis, as might also those who could find accommodation for reacting animals on a separate farm or in entirely separate buildings, and the Institute of Animal Pathology at the Royal Veterinary College had recently made an offer to lend its assistance to the owner of any pedigree herd who was prepared to carry out the measures actually necessary to that end.

Because it was not possible to put in force the drastic measures which would be necessary to eradicate tuberculosis within a prescribed period, it was necessary to enforce such measures as appeared to be practicable and necessary to prevent or diminish the cases of human infection from cattle. In the past very exaggerated views had been held regarding the danger of infection through meat, but at the present time there was general agreement that milk was the great vehicle of human infection, and that cases of transmission of bovine tubercle to man would be greatly diminished if one could cut off from human consumption the milk which came from cows which were actually infected with the disease. This was the object aimed at by the Tuberculosis Order which came into force in 1913 and the slightly modified Order which replaced that in July, 1914. The suspension of the latter Order on the outbreak of war was a misfortune, and if the subsequent discussion indicated that those present were in sympathy with the proposal he would be prepared to move a resolution to the effect that the reintroduction of the Order was urgently necessary in the interests of public health.

Bovine Disease as a Vaccine.

Professor S. LYLE CUMMINS said, with reference to Sir John McFadyean's question about the importance of bovine tuberculosis as a disease affecting man, that it raised several acutely controversial points. In Professor Cummins's opinion, when questions proved to be acutely controversial it was generally found that no very certain knowledge existed on either side. In a sense this was true as to the importance of bovine tuberculosis in this country. On one side much knowledge was being gained at the present time through researches of Dr. Stanley Griffiths at Cambridge and of others, some actually present at this meeting. It could be stated without any hesitation that bovine bacilli did cause fatal disease in human beings. It was known that they caused much of the abdominal tuberculosis of children, and it was also true that they take their share in producing tuberculous meningitis. As to the possibility of milk charged with bovine bacilli having a beneficial action as a vaccine, we were on much more uncertain ground.

There was, he went on to suggest, a great deal of evidence to show that the human race, in England at least, did owe a considerable amount of immunity to the ingestion of bovine bacilli in milk. Some support for this theory was to be found, he thought, in recent statistical records published by Dr. J. Brownlee, in which it had been shown that there were two important types of mortality from pulmonary tuberculosis in this country—the one affecting young adults and being especially prevalent in the Shetlands, in Wales, and in Ireland, the other leading to a mortality in middle-age, and being commoner in our large towns. It had been shown that there was a definite co-relation between the middle-aged type of mortality and milk-supplies contaminated with tubercle bacilli, but no such co-relation could be traced as between contaminated milk and mortality of the young adult type. As the middle-age mortality represented, presumably, a type of the disease on the whole more benign than that associated with earlier deaths, it was probable that some factor of resistance was operative in the one and absent in the other. Such a factor might perhaps depend on immunisation following small bovine infections in early life. But while thinking that such a theory was not merely tenable, but probable, Professor Cummins was far from advocating the deliberate use of contaminated milk for the purpose of obtaining immunity. Even assuming that such milk did actually act as a vaccine, it must be regarded as a very dangerous one, because the doses could not be controlled, and a massive dose would certainly lead to serious illness and perhaps death.

Under these circumstances Professor Cummins was prepared to support strongly the views expressed by Sir John McFadyean that every possible effort should be made to provide milk as free as possible from tubercle bacilli. He quite agreed with Sir John McFadyean that the complete elimination of bovine tuberculosis was out of the question as a practical measure, but he thought that if our efforts for a pure milk met with success we might reasonably hope so to diminish the number of tubercle bacilli in milk-supplies that there would be no danger of clinical disease and every prospect of the acquisition of relative immunity. When all was said and done, far the most important type of tuberculosis in this country was pulmonary tuberculosis, a disease caused by the human bacillus. Apart from the question of infection by bovine tubercle bacilli, there were other very strong reasons for wishing for a purer milk-supply. Many other diseases besides tuberculosis could be caused by contaminated milk. There was no doubt that the nutritive substances in milk were in very great dilution, and that the transport of milk involved the conveyance of very large volumes of fluid in proportion to the amount of nourishment contained therein. It was to be hoped that the physiologists might ultimately be able to say for certain whether the properties lost in the preparation of dried milk powder could be substituted efficiently by the addition of other articles to the diet of children.

The Rousing of the Public.

Sir **CLIFFORD ALLBUTT** said that he did not intend to detain them by a survey of the well-worked field of tuberculosis, of which many of his hearers indeed knew more than he did; yet he would try to say something new on the subject, even if it were paradoxical; as, indeed, it must be. Of the devastation caused by this virulent pest he need not speak, but as Robert Burns thought that there might be something to be said even for "Old Nickie-ben," so perchance to the evil spirit of tubercle some beneficent by-product might be credited. He remembered in the early days of his practice in the north how in the valleys of the Dales enteric fever was rampant and endemic; the farmsteads were foul with stenches, vermin, and disease, but the farmers said that a good manure heap did no one any harm. However, the discovery of the exact causes of typhoidal affections led to a conversion of people who before had turned a deaf ear to all arguments. So it was with tubercle; you might as well have argued with one of his bullocks as with the farmer on the intimate causes of this disease also, until the discovery of the tubercle bacillus aroused the public to a sense of the intimate and subtle virulence of germs of disease which could be neither seen nor handled. Tuberculosis, then, was our schoolmaster to drive into us these truths; a schoolmaster which chastised us with scorpions indeed, but began its serious lessons with those innocents the butcher and the milkman. No less had been the revelations on glanders and the marvellous results in the war of mallein vaccines—results which are almost incredible when compared h the ravages of the disease in former campaigns. e the education began with the stableboys. Thus the lessons of many such diseases had at last persuaded the man in the street to listen to the truths and prophecies of science.

The Rôle of Comparative Pathology.

Sir Clifford Allbutt continued :—

Let me now bring before you lesson the second, which is to avoid a rush to the other extreme—namely, an unreasoning cry for "results." Our campaign against tuberculosis is proving to the layman that, as in the field so in the laboratory, times and seasons are not to be controlled nor reckoned upon. A long cleaning of the land comes first, then after the fallow we have to plough and harrow to make a fine tilth, then to await due weather to sow the seed, then to keep patience during the long dormancy of seed apparently dead in the soil; and then again many a contingency before harvest is secured. If we are to solve these problems we need capital, time, and patience on the part of those awaiting our results. They cannot be hurried. In the schools maxims can be instilled in some order and with expedition, but discovery, the work of the universities, cannot be hurried nor produced to time. The third lesson of our schoolmaster is that if we are to understand the laws of disease in any one field we must coördinate it with work in other and allied fields of pathology. Every study but medicine has recognised and pursued the comparative method—anatomy, history, religion, law, philology, and so on. Medicine alone fails utterly to see the great work before it in this enlarged realm of research. We shall never understand the diseases of man until we study also side by side with them the diseases of plants and animals. For this reason I welcome to-night most cordially our veterinary visitors and the presidency of Sir John Bland-Sutton, one of the rare links of comparative pathology. Let us learn that the pathological relations of the humblest animal or plant may serve to throw into light fertile general laws and principles. Every moment of our lives we are dependent upon unicellular plants for good and evil. Who would have supposed that the harvest of herrings would appear to depend upon the changes in the sunspots! Now principles cannot be parcelled out between the several aspects and departments of medicine. Some beginning with comparative pathology we are making by coöperating with our veterinary brethren on this occasion, but it is a small beginning; we need far more than this. Fusion between two fields of medicine so different as theirs and ours is impossible, but coöperation and constant mutual enlightenment on systematic lines is essential if we are to comprehend their work, and they in like manner ours; for evolution is one of the keys to pathology as to biology. It is with the greatest anticipation of such a renewal of medicine that I have heard, on some such lines as these, of the election of a committee of which Sir David Prain is the chairman. This is one of the ameliorations we owe to our harsh and cruel schoolmaster tuberculosis. Specialise we must, especially in practice; but it is the place and function of the universities to counteract this narrowness by a wider outlook and by a clear-eyed faith in the results—some ready, some deferred—which we shall gather in if we work together in an endeavour each from our own side to throw crosslights upon the researches of workers in other departments of medicine. Until we establish institutes of comparative pathology our science and art will tarry on the way.

Age Distribution of Human and Bovine Infections.

Dr. A. C. **INMAN** said that the scientific study of tuberculosis became possible when in 1882 Koch discovered the causative agent of the disease. The distinction between the human, bovine, and avian types was another advance and had allowed us to obtain some valuable knowledge as to the sources of infection and as to the relative importance of infection from man to man and from the consumption of foodstuffs contaminated with the bacilli of bovine origin. For this country the study of the types of bacilli infecting man

TABLE I.

Age-period.	No. of cases.	Human.	Bovine.	Human and bovine.	Atyp.	% bovine.
0 to 5 years. ...	196	127	65	2	2	34·2
5 to 10 years....	265	189	70	1	5	26·8
10 to 16 years....	127	105	16	—	6	12·6
16 and upwards.	341	313	18	2	8	5·9
*Total	929	734	169	5	21	18·70

had been very carefully undertaken, and we owed to the Royal Commission on Tuberculosis, and more especially to the extended work of Dr. Stanley Griffith and Dr. A. Eastwood, an accurate knowledge of the relative frequency of infections by the human and bovine types in the various types and forms of tuberculosis, as was shown by Table I. It would be seen that consumption was nearly always due to infection by bacilli of the human type.

Table II. showed the results of sputum cultures:—

TABLE II.

—	No. of cases.	Human.	Bovine.	Atypical.	% bovine.
All ages	212	205	3	4	1·41

Whilst the bacilli recovered from the glands in the neck occurring in children during the first decade of life were, in the majority of cases, of the bovine type, these studies had shown us the importance not only *of taking steps to prevent infection from man to man,* but also to prevent the consumption of foodstuffs contaminated with bacilli of the bovine type. Evidence obtained from the post-mortem examinations had shown us that under the age of 18 years tuberculosis was relatively *uncommon* but very *fatal*, whilst in adults it was common but largely latent and non-fatal. (Table III.)

TABLE III.

Subjects under—	No. of post mortems.	Free from tuberculosis.	Tuberculous.	Fatal tuberculosis.	Non-fatal tuberculosis.
18 years of age ...	88	73	15 (17 %)	11 (73·3 %)	4 (26·7 %)
Adults	420	29	391 (93 %)	110 (28 %)	281 (72 %)

Another important *fact* learnt from post-mortem examination was that *the healing of a tuberculous* lesion consisted in the throwing up of a defensive barrier and the shutting off, rather than the extermination of, the bacilli. Fully virulent living bacilli might be recovered from old "healed" tuberculous lesions even if these had *undergone* calcification. (Rabinovitch, Burnet.) V. Pirquet's testing of 693 clinically non-tuberculous children with the cutaneous tuberculin test confirmed the findings of the post-mortem room. By the age of 10 years 35 per cent. reacted positively, and by the fourteenth year the percentage had risen to over half (55 per cent.). The *observations of Franz on* apparently healthy soldiers of (1) a Bosnian regiment recruited from a district where tuberculosis was rife, and (2) a Hungarian regiment recruited from a district poor in cases of tuberculosis, bore repeating because of their *importance in connexion* with *the incidence of tuberculosis* infection in young adults, and the value of the tuberculin test in the diagnosis of tuberculosis.

To eradicate the disease from man effectively it would seem necessary to have a certain preventive against the infection. This we did not possess. But we did know the sources of infection, and it was our duty to protect everyone from such sources. It was distressing under the circumstances to read in Dr. Marcus Paterson's book the statistics culled by Dr. Sutcliffe, of the Ipswich Sanatorium, on the use of the sputum flask by tuberculous patients in this country as recently as 1918. Of patients admitted to the sanatorium on the advice of medical men 93·75 per cent. had sputum before admission. In 57·77 per cent. bacilli had been found previous to admission. Only 8·88 per cent. of those with sputum arrived at the sanatorium with a flask. Paterson also *pointed out that the control of milk,* butter, and cheese could *be much more efficiently carried out* than was the case to-day.

Three Desiderata.

In the absence of a certain preventive against infection we required the following desiderata urgently: (1) A method of diagnosing the disease in its earliest stages; (2) a successful method of treating the disease; and (3) a method of ascertaining that the disease was cured.

1. *A Method of Early Diagnosis.*—In the case of tuberculous infection we had as yet no certain means of diagnosing the disease in its earliest stages. Owing to the large number of apparently healthy persons who gave a positive reaction, the tuberculin test had proved to be of but limited value in the early diagnosis of the disease. The demonstration of tubercle bacilli in the sputum only became possible when the tuberculous ulcer communicated with a bronchus—i.e., the bacilli were not demonstrable in the earliest stages of the disease. The great value of the test, however, could not be too strongly insisted upon from the point of view of the public health. It should be possible to examine the sputum of all patients who consulted a doctor for cough with sputum, whatever physical signs or symptoms they *presented.* Even to-day it was not uncommon to find *numerous tubercle bacilli* in the first sample *of sputum* examined *for* a *patient who* had been under *medical* treatment *for months*. From the patient's point *of view the* examination was one of very considerable *importance, for* the tuberculous focus in the lung was, when tubercle bacilli were present in the sputum, in communication with the outside world, and was liable to become contaminated with bacteria other than the tubercle bacillus. From the following table, summarising the results of an investigation which he had carried out in 1912, it would be seen that secondary infections were by no means uncommon in "open" pulmonary tuberculosis. (Table IV.):—

TABLE IV.

—	Febrile cases.	Afebrile cases.
A. Infection by T.B. and secondary organisms	28 (87·5%)	13 (54·1%)
B. Infection by T.B. alone	4 (12·5%)	10 (41·6%)
C. Infection by secondary organisms alone	0	1 (4·1%)
—	32	24

It was an urgent matter to place the patients in as pure an atmosphere as possible and away from *congested areas in* which the air was liable to be polluted with *catarrhal micro-organisms.* There was a *striking contrast* between the bacterial *flora of* sputum *in London* and that of patients living in pure country air. He believed that the good results obtained *from the so-called open-air treatment of* pulmonary tuberculosis was largely to be attributed to this limitation *of the sources of* secondary *infections.* The *technique of the* tuberculo-opsonic index was difficult, and its routine use, as in a large institute, was a very great strain on the individual who carried out the test. An analysis of 250 cases of doubtful pulmonary tuberculosis performed in the routine laboratory tests of the Brompton Hospital gave the results shown in Table V.:—

TABLE V.

Cases without T.B. in sputum.	No. of cases.	Positive.	Negative.
Clinically tuberculous disease ...	56	48 (85·71%)	8 (14·23%)
Doubtfully tuberculous disease ...	134	91 (67·91%)	43 (32·08%)
Clinically non-tuberculous disease	60	4 (6·66%)	56 (93·33%)

In 100 cases with a positive index and no tubercle bacilli in the sputum special care was taken over a subsequent period *of* about two years to try to find tubercle bacilli by numerous examinations of the sputum, and in *14 cases the bacilli were found confirming the diagnosis.* In a small series *of* cases, *doubtfully tuberculous,* and admitted to the hospital *for diagnostic purposes the tuberculo-opsonic index test* and the complement-fixation test *were carried* out on each patient. In 21 out *of 30 cases (70 per cent.)* the two tests agreed; In 5 out of 30 cases (16 per cent.) the T.O.I. was positive and the *C.F.T.* was negative, and *in 4 out of* 30 cases (13 per cent.) the T.O.I. was negative *and the* C.F.T. was positive. In a series of 42 cases at the King Edward VII. Sanatorium, Midhurst, *Dr.* Radcliffe and *Dr.* de Wesselow made a similar observation. In 32 cases (76 per cent.) the two tests agreed; in 7 (16 per cent.) the T.O.I. was positive and the C.F.T. was negative, and in 3 cases (7 per cent.) the C.F.T. was positive. Further work was necessary to enable us fully to understand the mechanism of the test. In 1913 an investigation was carried out at the Brompton *Hospital on* the value of the complement-fixation test as an aid to early diagnosis. Besredka's antigen was used, and *though the* results were encouraging it was found that the antigen was not truly specific, for positive reaction was obtained with syphilitic non-tuberculous sera. In a series of 107 consecutive cases admitted to Dr. W. C. Bosanquet's wards the bloods were sent to the laboratory for examination, and *Dr. Bosanquet* independently recorded his diagnosis after due clinical observation. There was a remarkable agreement in the diagnosis. In 1920, several years after the bloods had been examined, he (Dr. Inman) had tried to find out what had happened to those patients who had had no tubercle bacilli in their sputum at the time of the blood test. Only 29 cases could be traced. McIntosh and Fildes had suggested in 1914 the use of a fresh suspension of living tubercle bacilli as an antigen in the complement-fixation test for tuberculosis.

Such an investigation had been instituted at Brompton, and the test promised to be one of real utility. Before any considered announcement could be made, however, further research was needed, more especially with regard to the specificity of the reaction, and to state the activity of the lesion in those cases in which the reaction was positive. Infallibility could not be expected of any biological test, and it was doubtful whether, seeing that the general population of this country was largely tuberculous, such tests could ever occupy quite the position of practical utility in the diagnosis of tuberculous infections as the Wassermann reaction did in the diagnosis of syphilis.

2. *A Successful Method of Treatment.*—There was no known cure for tuberculosis. He believed, however, in the importance of the principles of auto-inoculation of bacteria and their products enunciated by Sir Almroth Wright. As the results of laboratory experiments the importance of absolute immobilisation of a tuberculous focus from which excessive auto-inoculations were proceeding received specific confirmation. The revelation of a rich content in antibodies in certain pleural effusions had led Perkins, Young, and Meek to inject such fluids for therapeutic purposes in seriously infected cases of pulmonary tuberculosis, with encouraging results. He believed that the intelligent administration of tuberculin and vaccines prepared from secondarily infecting microbes might still serve to convert a seemingly hopeless outlook in some cases into one of so great amelioration that life for the patient became tolerable and even enjoyable.

3. *A Method of Ascertaining whether Cure Took Place.*—No certain means of ascertaining when a tuberculous infection was cured as yet existed. He spoke of the vital-capacity test as formulated by Dreyer. In a preliminary series of 150 cases of pulmonary tuberculosis weighed, measured, and treated by Dr. L. S. T. Burrell at the Brompton Hospital in London, Professor G. Dreyer at Oxford, by calculation of the figures sent to him by Dr. Burrell, was able to classify these persons as normal individuals, or as examples of mild, of moderate, or of severe pulmonary tuberculosis, in practically absolute agreement, as afterwards appeared, with the clinical diagnosis and classification made at the time at Brompton.

In proved tuberculous cases he believed that a series of blood examinations as regards the Arneth count might prove to be of distinct value in the testing of a case as to arrest of the disease. Dr. Treadgold, working in his laboratory, had come to the conclusion that a left shift under 200 in old cases of "clinical arrest" was suggestive of recurrence, and called for minute and careful re-examination. He urged that a record of the serum reactions, quantitatively estimated, should be kept of all cases evacuated from sanatoriums as "clinically arrested." He thought that most of the patients so discharged were probably still in need of treatment, and their lesion was still in communication with the blood and lymph stream. The verification of this might lead to a prolongation of treatment and a diminution in the number of relapses.

Influence of Environment on Resistance.

Dr. **HALLIDAY SUTHERLAND** said that an increase of knowledge regarding the details of tuberculosis could never lead to more than partial success in the task of eradication unless there was agreement concerning certain general principles. Since the discovery of the tubercle bacillus medical opinion on the ætiology of the disease had swung from one extreme to another. If asked the cause of tuberculosis the majority of people would answer "the tubercle bacillus." That answer was wrong. Tuberculous infection was ubiquitous, and after middle life practically everyone was infected. If the tubercle bacillus was the cause of the disease—using the word cause in its true sense—then mankind would have been decimated long ago. Tuberculosis as a disease was produced by two factors—infection and resistance of the tissues. The relation of these two factors was shown in the animal experiments of Trudeau in 1885. When resistance was unimpaired it was difficult to infect either a man or an animal, and when man lived under conditions in harmony with nature tuberculosis was a rare disease. Even to-day there were primitive races free from tuberculosis, and in the south of Spain amongst the fighting bulls living on the open plains tuberculosis was very uncommon, although domestic cattle in the same country were notoriously tuberculous. Such was the influence of environment on resistance. If resistance was unimpaired, either a massive dose of bacilli or prolonged exposure to infec- s necessary for the development of the disease, was easier to induce the disease in a starved than in one well fed. To eradicate the malady it was necessary to raise or to maintain resistance, and to prevent infection.

As the bovine tubercle bacillus had been recovered in over 50 per cent. of cases where tuberculosis attacked the glands, bones, and joints of children, it was probable that some 10,000 children died every year in consequence of drinking tuberculous milk. Sir John McFadyean had said that to eradicate the disease in cattle it would be necessary, amongst other things, to slaughter 1,000,000 animals. That was not the experience of the American Government. By the Bang system tuberculosis could be eradicated from a herd within seven years, and it was only necessary under that system to slaughter the animals having advanced disease. As tubercle bacilli were present in the milk from animals whose udders were not affected, the Tuberculosis Order of 1912 would only check the gross infection of milk, and could not secure a tuberculosis-free milk. There were two extreme views on the question of tuberculous milk, and in attempting to reconcile these extremes by adopting a neutral attitude Professor Cummins had involved himself in certain very obvious contradictions. Professor Cummins deprecated the gross infection of milk, welcomed the Tuberculosis Order, and hoped that we should benefit by drinking the slightly infected tuberculous milk that would continue to exist after the Order was put in force. It was true that Dr. Brownlee had shown the chronic type of pulmonary tuberculosis to be correlated with milk, but there were many other factors with which it might be correlated. Those who believed in the benefits of drinking tuberculous milk should advocate the vaccination of children with attenuated cultures of tubercle bacilli. The dosage could then be controlled, and those who urged this plan would at least be logical. That plan would not be advocated. The work of Arloing had first shown that immunity conferred in this way was both partial and transient. Calmette more recently had shown that the resistance of an infected animal could be raised and prolonged by these measures. If Dr. Brownlee's views were correct then this partial immunity would lead to an increase in the number of chronic cases, whereby the amount of infection amongst the population would be increased. Those who played with the question of tuberculous milk would do well if they followed their opinions to a logical conclusion. Remarks by medical men on the advantages of tuberculous milk did a great deal of harm, not amongst the medical profession, who were able to assess their value, but amongst dairy farmers and the general public. These statements were seized upon by the trade and used as an argument against legislation, which, however imperfect it might be, had for its aim the preservation of the life and health of children. Professor Cummins had also said that the milk trade was in an unsatisfactory economic condition on account of the bulk of fluid milk and of the difficulties in transport, to overcome which he advocated dried milk. As dried milk was much more expensive than fresh milk this proposed remedy was obviously economically unsound.

By far the greatest source of infection was from human beings, and in order to eradicate the disease it was necessary to correct the faulty environment whereby resistance had been lowered, and to check the amount and spread of infection. It was impossible to alter the general defects of our civilisation to any material extent, but it was possible to alter the environment of the individual patient. Unless this was done in the early stages of the disease the change came too late. That meant early diagnosis. Everyone would welcome the advances in bacteriology of which Dr. Inman had spoken, and to which he had contributed so much, but there was a real danger lest a type of practitioner was evolved who relied solely on a laboratory for diagnosis and failed to use the senses that God had given him. In spite of many difficulties it was already possible by means of clinical methods, X rays, and the tuberculin subcutaneous tests to make a firm and accurate diagnosis of tuberculosis months and even years before tubercle bacilli appeared in the sputum. A chair of tuberculosis should be created in every university, and competent clinicians, having special experience in this disease, should be appointed to teach the students.

Once the disease had been diagnosed the next step was to provide adequate treatment for patients in all stages of the malady. Sir Robert Philip's coördinated Edinburgh system provided for all contingencies. The tragedy was that the system had not been carried out on the lines advised by the Departmental Committee in 1912. Sanatorium results were bad because the sanatoriums were filled with advanced and dying cases. When early cases were sent and kept for an adequate period the results were uniformly good. As tuberculosis was essentially a disease of civilisation, there was no short cut to its control and eradication.

Combined Medical and Veterinary Effort.

Professor **F. HOBDAY** had no doubt as to the value, in any scheme for the eradication of tuberculosis, of collaboration between the medical and veterinary professions, as each was well acquainted in their respective everyday lives with the disease in all its forms. The question of clean milk certainly could not be settled except by combined action between the two.

In his original paper he had purposely generalised in various diseases communicable to man, with a view to emphasising the importance of united effort on the part of the workers in human and veterinary medicine; but when, at the request of the members present, the discussion was adjourned and it was suggested that one of the subjects only should be taken, he readily acquiesced, and eradication of tuberculosis from man and animals was chosen. It was the subject which he had suggested as being of far too great importance to be grouped with others, one which must of necessity be taken by itself, and one about which every scientific worker, whether in the laboratory or clinical sphere, could say something. Particularly was it of importance just now on account of the new hopes which were being raised by the report of the work recently done on immunity by vaccinations, and here again the observations made upon animals must take first place. Much for mankind depended upon the results here to be attained, and the whole research was still a further corroboration of the advantage of collaboration between those who had expert knowledge of the normal habits of animals as well as man. Taking all the diseases originally mentioned in his lecture, and even if the cases of actual transmission were, as Sir John McFadyean had said, only enough for the average man to see once in three years or once in ten years, this was all the more an argument for keeping them out of the country, and it was all the more to our credit if we did this. What would be the position now if the veterinary profession had not done its duty in the past with regard to glanders and rabies? It was to the veterinary side of comparative medicine that the country owed this excellent position at the present time, and if we could find the way to do as much for tuberculosis of cattle as we had done for the eradication of glanders from horses we should again have rendered mankind a service. As regarded tuberculosis in cattle, it was possible to eradicate it by the aid of tuberculin if cost was no objection. It was the cost together with the question of the milk-supply which stood in the way. That bovine infection was a reality was shown by statistics brought forward that evening by Dr. Inman, who had told us that 18·7 per cent. of all cases were of bovine origin; that in tuberculosis of the glands of the neck of very young children the proportion went up to 85 per cent., and between 5 and 10 years of age 65 per cent., whilst another speaker had said that of this form of tuberculosis an average of 10,000 children died annually. He thought that the discussion and the interest shown by the mixed assembly of medical and veterinary professions proved the truth of the last paragraph of his original paper: "that in the combat against disease the workers in human and veterinary science go over much the same ground, and that by working in unison much valuable time might be saved and much better results would be attained than if each kept itself in its own water-tight compartment."

A Unanimous Resolution.

The following resolution was passed unanimously:—

That the Fellows of the Royal Society of Medicine and officers of the National Veterinary Association, assembled in joint meeting, are of the opinion that the prevalence of tuberculosis among cattle in this country continues to be a serious menace to the health of human beings, and that to counteract this danger the reintroduction of the Tuberculosis Order, which was suspended in 1914, is urgently required.

SECTION OF PATHOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on March 15th, Dr. W. S. LAZARUS-BARLOW, the President, being in the chair.

Dr. J. A. MURRAY read a paper contributed by Dr. W. H. WOGLOM and himself on Experimental Tar Cancer.

Dr. A. J. EAGLETON read a paper on

The Standardisation of Antipneumococcal Serum.

The work of American bacteriologists, he said, had differentiated four groups of pneumococci. Groups I., II., and III. were definite entities, there being three subgroups to Group II. Group IV. consisted of a heterogeneous collection of pneumococci unrelated to each other, or to the first three groups. Therapeutic serum (type I.) had been used in America with encouraging results. There was less evidence of the value of types II. and III. sera, and American opinion was at present against their use for therapeutic purposes. A serum for therapeutic use had been prepared at the Wellcome Physiological Research Laboratories by immunising horses with a type I. pneumococcus. It had been tested (almost entirely with an English strain) by a method almost identical with that used in America. The test consisted essentially in the titration of 0·2 c.cm. of serum against different doses of living pneumococcus culture. Mice are employed and the injections made intraperitoneally. Adequate controls must be made, and all injections done in duplicate. Care must be taken in dilution of the culture prior to the test, as very grave errors could be introduced by carrying over organisms from tube to tube.

Upon three main factors the success of the test depended:—

(1) *The mice.*—Gaertner infections accounted for many failures; in other cases, although no specific extraneous infection could be found, the animals succumbed irregularly from general deficiency of resisting power. Feeding must be carefully watched, exposure to cold avoided, and the animals should be kept under experimental conditions for at least one day before injection.

(2) *The media.*—The virulence of a culture might apparently be lost by growth on unsuitable media; the virulence returned when the organism was given a suitable environment. The broth must not be more acid than pH = 7·2, and to maintain this reaction a heavily buffered peptone was necessary. The medium should not be over-heated. Cultures maintained on horse-blood agar had lost their virulence, to regain it on transference to sheep- or rabbit-blood agar. This was correlated with the fact that certain horses contained a normal antibody to the pneumococcus. Rabbits did not. Sheep had not been tested. Two interesting speculations arose out of this: (*a*) Was the presence of normal antibodies in the blood of some animals responsible for variations in growth of micro-organisms on media containing unheated blood; (*b*) did it help to explain the value in some cases of non-specific horse-serum therapy.

(3) *The micro-organism used.*—The culture must be virulent. The strains used were virulent when received. They had not been passaged and were still virulent. While not stating that passage is unnecessary for maintaining virulence, the workers held that too much attention had been paid to it, and too little to the media employed.

Serum made to protect against type I. American strain was efficient against English strains. Protective serum had also been made against type II., but by the test described this had not at present the same high degree of potency as the type I. serum. Large doses had been given intravenously to rabbits without producing any untoward effects.

Dr. NATHAN RAW read a paper on the

Attenuation of Tubercle Bacilli.

He showed numerous cultures and specimens of tubercle bacilli which had been continuously subcultured for 14 years. These bacilli were now avirulent and non-tuberculigenic, after repeated tests on susceptible animals. The object of this work was to endeavour, if possible, to find a specific remedy against tuberculosis and to protect children of tuberculous stock who were exposed to infection in the home.

CARDIFF MEDICAL SOCIETY.

A MEETING of this society was held on March 8th, Dr. W. MITCHELL STEVENS in the chair, when Professor T. GRAHAM BROWN delivered an address on

Experiments on the Brain.

He first sketched the history of the work on brain areas, and then described certain experiments carried out on chimpanzees. Stimuli applied to the motor areas, although at first subminimal, were found, when repeated, to cause movement, an effect known as "facilitation." Similar stimuli applied to one area made neighbouring areas sensitive to subminimal stimulation, an effect known as "activation"; this effect was due to fibres in the cortex connecting neighbouring areas. Destruction of motor areas in the cortex was followed by only temporary paralysis, and complete restitution of movement was soon regained; this result followed when the cortex was ablated on both sides. This restitution also followed the destruction of sensory areas on both sides and of the motor area on one side. Professor Brown pointed out that the work was as yet far from complete, but he put forward the suggestion that the deeper structures of the brain controlled postural movement, while the cortex was more concerned with fine manipulation.

LIVERPOOL MEDICAL INSTITUTION AND MANCHESTER MEDICAL SOCIETY.

A JOINT meeting of these societies was held at Liverpool on March 3rd, the President of the former, Dr. J. E. GEMMELL, in the chair.

Vascular Lesions of the Brain.

Professor E. S. REYNOLDS mentioned some points arising in connexion with vascular lesions of the brain, quoting illustrative cases. He specially referred to meningeal hæmorrhage occurring during birth, to emboli and their results, and compared these in their symptoms and course with thrombi and hæmorrhage. He alluded to the difficulty which often occurred in diagnosing whether a hemiplegia was due to thrombus or hæmorrhage, and the consequent difficulty in treatment.

Posterior Rhizotomy.

Sir WILLIAM THORBURN gave an account of cases of Posterior Rhizotomy and of Drainage of the Spinal Theca. As regards rhizotomy, he related several personal cases in which the operation had been performed for gastric crisis, and analysed the published records. With regard to rhizotomy for pain, he indicated, again from personal cases, why in many instances relief was not to be anticipated and why the results are less satisfactory than in gastric crises. He did not recommend Foorster's operation for spastic paraplegia. He then referred to cases resembling transverse myelitis, in which drainage of the theca spinalis was followed by rapid recovery. He recalled the earlier work of Horsley on so-called chronic spinal meningitis, and strongly urged the exploration of any doubtful cases of this type, pointing out that in practised hands the operation of laminectomy is as safe and reliable as is laparotomy.

Diathermy and Pharyngeal Operations.

Sir WILLIAM MILLIGAN read a paper upon the Treatment of Inoperable Malignant Growths of the Pharyngeal and Epilaryngeal Regions by means of Diathermy and Radio-diathermy. He pointed out the type of case suitable for diathermy treatment and described the rationale of the treatment. In cases where diathermy was done close to large blood-vessels great care had to be taken, as otherwise there was a risk of sloughing of arterial walls and severe secondary hæmorrhage. In many cases it was advisable to tie the main blood-vessels leading to the affected regions. Diathermy treatment had the advantage of sterilising the tissues, blocking the lymphatics and small blood-vessels, and of readily destroying malignant cells owing to their having in all probability a lower vitality than normal cells. In cases where the growth to be treated was situated in the immediate neighbourhood of the larynx, it was advisable to perform a preliminary tracheotomy. In small growths the best results appeared to follow the use of a current of from 500 to 900 milliampères, but in large growths of one to two ampères were necessary. Where there was much necrotic tissue it was a good plan to perform a preliminary scraping, great care being taken, however, to avoid any bleeding as far as possible. The pain produced was, as a rule, not great until about the eighth or tenth day, when it was considerable owing to the separation of the slough and the formation of a raw granulating surface. The presence of glands did not negative diathermy operations, and glands might be treated either by diathermy itself or by intensive X ray treatment. Where intensive X ray treatment was used it was advisable to desensitise the skin either by the application of pressure or by the subcutaneous injection of salt solution. The advantages of diathermy were: 1. That it might be employed when ordinary surgical procedures are impracticable. 2. That it does not produce much, if any, shock. 3. That with reasonable care it is a bloodless procedure. 4. That it has the merit of sterilising the tissues, blocking vascular and lymphatic vessels and preventing [illegible]mination of the cancer cell. 5. That it frequently affords relief from painful symptoms and mechanical difficulties in cases surgically hopeless. 6. Septic and broncho-pneumonia are much less frequent than after cutting operations. Its disadvantages are: (1) that it destroys both healthy and diseased tissues. (2) that the walls of adjacent blood-vessels may become softened and secondary hæmorrhage result; and (3) where the skin is involved keloid cicatrices may result. He referred to a series of inoperable surgical cases where, by means of diathermy, life has been prolonged for from two and a half to three years with complete comfort.

Variations of the Normal Stomach.

Dr. A. E. BARCLAY discussed the Variations of the Normal Stomach. He maintained that the old anatomical pictures were caricatures, and that the distortions were due to the action of formalin or other preservatives, coupled with the effect of rigor mortis. Essentially the stomach was a living muscular tube, whose very varied alterations in appearance was largely due to alterations in muscular tone. The tonic action was a function of the living muscle, and could only by studied in life by means of X rays. The main function of this tonic action was to stabilise the stomach so that it maintained the contents in tubular form in spite of gravity. When tone relaxed the contents descended to the lowest part of the stomach. He demonstrated models of normal empty and full stomachs, and also a series indicating the way in which its shape was changed by the alteration of posture. Tonic action was responsible for the maintenance of the shape of the normal stomach, and he insisted that transitory loss of tone and gastroptosis were simply variations of the normal. He then dealt with the musculature, and laid great stress on the great importance of the innermost layer, the incomplete and powerful band of oblique fibres that passes down on either side of the lesser curvature and illustrated the band by a series of dissections by Jefferson. He pointed out that in atony this oblique band was apparently unaffected, while the rest of the muscle was thinned out. In gastroptosis, on the other hand, the oblique fibres were elongated proportionately with the other coats. He also showed slides of a type of normal stomach which he called the "cup and spill." This curious shape, he suggested, was due to over-contraction of this oblique band without a corresponding contraction of the other coats. From these observations he deduced that the oblique fibres could act entirely independently of the other coats, and that, in all probability, the anatomists would find that they had a separate and independent nerve-supply.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

THE eighth meeting for session 1920–21 was held in the Faculty Hall on Feb. 18th, when Professor ROBERT MUIR gave a lecture, with microscopic demonstration, on

Hæmochromatosis and Bronzed Diabetes.

The development of our knowledge of the subject was briefly sketched, and it was pointed out that the essential pathological feature was the deposit of iron-containing pigment in great amount and in unusual positions, this resulting in hæmochromatosis; and that diabetes resulted only when the lesion in the pancreas was of sufficient degree, there being cirrhosis in this organ as well as in the liver. Two cases were described in which both bronzing of the skin and diabetes were present, and reference was made to the estimations of iron made in one of these along with Professor Shaw Dunn. An account was also given of two, and possibly three, cases at an early stage of the affection, and from these the inference was drawn that the earliest lesions were cirrhosis of the liver and pancreas, with deposits of hæmosiderin in these organs and in the retro-peritoneal lymphatic glands. In the pancreas the changes occurred at an earlier period in the secreting epithelium than in the islands of Langerhans, but the results did not warrant a conclusion as to the relation of the lesions in these structures to the onset of diabetes.

The lecturer contrasted the deposits of pigment with those occurring from abnormal hæmolysis, and pointed out that they differed both in amount and in distribution, those in hæmochromatosis being much greater and occurring in sites, such as thyroid, heart muscle, skin, stomach, &c., in which hæmosiderin resulting from hæmolysis did not occur. From these facts and from the fact that in hæmochromatosis there was no evidence of increased blood destruction or regeneration it was not justifiable to conclude that the iron pigment was actually derived from hæmoglobin. There might be an inability to use up again the iron derived from normal hæmolysis, but in this case the peculiar distribution of the pigment could not be explained.

The essential factor in hæmochromatosis appeared to be a special affinity of the tissues and organs for iron, and the source of the stored iron must ultimately be the iron in the food, but whether or not this passed through the form of hæmoglobin was not certain. The cirrhosis of the liver and possibly of the pancreas seemed in some way to be related to this abnormal metabolism of iron, but there must be some special factor, as in most cases of cirrhosis of the liver the accumulation of pigment was absent. The accumulation of iron must go on for a long period of time, sometimes for two or three years, even if all the iron in the food were retained. Reference was also made to recent analyses of food and excreta, indicating that there was an actual retention of iron.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

Teething.

A MEETING of this society was held on March 9th, Dr. L. E. V. EVERY-CLAYTON, the President, in the chair, when a discussion on Teething was opened by Dr. R. O. CLARKE, who began by saying he did not believe in the so-called symptoms of teething.

From the days of Hippocrates till the early part of last century "teething" was held to be the cause of all infant maladies, and some 50 per cent. of the infant mortality was attributed to it. A number of ridiculous superstitions arose, some of which survive to this day, such as the impropriety of healing a sore on a baby's head or curing an otorrhœa before the completion of dentition. In the middle of the nineteenth century doubts began to arise. In modern textbooks the subject was mostly dealt with by "hedging." The argument in one of these, that so many intelligent parents could not have been deceived, Dr Clarke held to be most fallacious, and he instanced the beliefs in witches, the evil eye, and overlookings which were upheld for centuries. After touching on views as to the process of eruption of a tooth, a process which he maintained was normally painless, he called attention to the fact that a baby is always cutting teeth from 6 months to 2 years old. He then went through the symptoms usually attributed to a baby being "about his teeth," such as dribbling, biting on hard objects, and so on, and gave an alternative explanation in each case. Disorders regarded as complications of teething, such as gastro-enteritis, and colds in the head, with consequent otitis, bronchitis, &c., were, he said, infective in origin in the first six months of life, and asked why their relapses after that date should be ascribed to teething? He did not deny that there was such a thing as painful dentition. Going through the various "scientific" theories advanced to support a popular idea, he said he could not see why reflexes from the fifth nerve should upset one system more than another.

Dr. Clarke said that there were two main classes of opinion. To those who really believed in "teething troubles" he had nothing to say, because their idea, often learnt at their mothers' knees, was as firmly fixed as their religious and political opinions. There were, however, those who, though not really believing in "teething troubles," yet thought it a harmless and eminently useful diagnosis, and it was to these that Dr. Clarke addressed his remarks. He firmly believed that nearly all minor ailments of babies were preventable, and that if medical men would instruct mothers how to avoid diarrhœa and colds they would get better results than by being content to say "It's teething." Moreover, the symptoms of early rickets, the most frequently overlooked of all diseases, were just those—convulsions and catarrhal infections—which were commonly attributed to teething.

Discussion.

The PRESIDENT confessed to a belief in teething as a source of rashes.—Professor F. H. EDGEWORTH thought it was improbable that any reflex irritation could provoke convulsions.—Dr. J. O. SYMES took the view that the belief in teething as a source of symptoms was a harmless and often comforting superstition.—Mr. W. R. ACKLAND spoke of the sudden relief to symptoms afforded by the opening of a gum, a fact corroborated by Mr. A. W. PRICHARD.—Mr. E. A. G. DOWLING attested the truth of the reference of aural pain to teething, and Dr. P. WATSON-WILLIAMS thought that the process of teething might actually lower the resistance of the ear to infection and predispose to otitis.—Mr. E. H. E. STACK showed that it was possible to distinguish between referred and direct aural pain.—Dr. R. S. STATHAM quoted experiences to show that in the second dentition it was sepsis that introduced an element of pain, and Dr. V. M. COATES spoke of bacteriological data supporting the infective theory of pain in the first dentition also.—Professor WALTER C. SWAYNE said that children's weights "mark time" and do not increase during teething, and observed that the coincidence of changes of diet with the period of teething might explain the coincidence of digestive disturbances with teething.—Dr. C. E. K. HERAPATH supported Dr. Clarke's view that it was time to relegate belief in teething as the cause of disorders to the realm of exploded myths.—Mr. G. F. FAWN gave reasons for believing that teething was often a painful process.—Dr. C. F. COOMBS suggested that the absence of complications from the second dentition supported Dr. Clarke's arguments. —Dr. CLARKE replied.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

AT a recent meeting of this society Dr. LESNÉ read a paper on

The Posology of Sodium Salicylate in the Child,

in which he emphasised the tolerance of the child for this drug and the good effects derived from its administration by enemata or intravenous injections in doses of 0·5 g. per c.cm. The tolerance to salicylates in childhood, shown by absence of tinnitus, delirium, and albuminuria, was doubtless due to the perfect condition of the renal emunctories in early life, as the salicylate appeared in the urine less than 24 hours after its ingestion.

The Hypodermic or Intravenous Injection of Allyltheobromine.

Dr. ROSENTHAL stated in a communication on this subject that though theobromine was regarded by Huchard as the most reliable diuretic, it was often ill tolerated in doses of 2 g. and a fortiori in doses of 3 or 4 g. On the other hand, allyltheobromine, which was 150 times more soluble than theobromine, could easily be injected in the form of a neutral solution hypodermically, intramuscularly, or intravenously. Dr. Rosenthal therefore recommended that in all cases of intolerance for theobromine allyltheobromine should be substituted in intramuscular injections of 0·30 g. twice a day. The intravenous method should be reserved for urgent cases or for those in which the presence of an œdematous infiltration contra-indicated the hypodermic route.

The Action of Heliotherapy and Phototherapy on the Præcordial Pain of Angina Pectoris.

Dr. ARTAULT DE VEVEY recorded two cases in which this treatment caused immediate relief and finally complete disappearance of anginal attacks occurring in patients with cardiac disease.

The Cholagogic Action of Polypodium Vulgare.

Dr. H. LECLERC stated, in a communication on this subject, that the rhizome of this fern, which was a favourite remedy in ancient times, was a powerful cholagogue without any irritative action. He related the case of a girl suffering from catarrhal jaundice whose symptoms had proved refractory to all the usual remedies, but soon subsided after the use of this rhizome.

The Treatment of Epidemic Encephalitis.

Dr. MULLER, of Liége, recorded three cases of the myoclonic form of epidemic encephalitis in patients aged 42, 33, and 15 respectively, in whom intravenous injection of iodine oil caused a rapid disappearance of the symptoms. The doses ranged from 6 to 15 c.cm. and from three to six injections were given in each case.

THE Chelsea Hospital for Women has received £100 from Mr. T. G. Sorby and £25 from Lady Nort towards the building of its nursing home.

Reviews and Notices of Books.

TUBERCULOSIS.

1. *Traité de Pathologie Médicale et de Thérapeutique Appliquée.* Tuberculose. (1) La Tuberculose en Général. (2) La Tuberculose de l'Enfant et de l'Adulte. Les Tuberculoses Viscérales. Edited by ÉMILE SERGENT, L. RIBADEAU-DUMAS, and L. BABONNEIX. Paris: A. Maloine et Fils. 1920 and 1921. Pp. 379 and 811. Fr.20 and Fr.35.

THESE two large volumes, which contain numerous black and white as well as coloured illustrations, include a series of articles on different aspects of tuberculosis by writers whose names are in themselves a certain guarantee of the value of the opinions expressed. Like most systems of medicine compiled by several writers, these volumes are good in parts; indeed, in most parts; as an index to the present vogues of treatment they are illuminating. More than 50 pages are devoted to an account of artificial pneumothorax treatment, and in the space of less than six pages vaccine therapy, including tuberculin, is handled with merciless scorn. Dr. Joussett stamps tuberculin as a pseudo-vaccine which both in theory and in practice is a gigantic failure. So it may be. But it is a curious fact that tuberculin therapy has survived for more than 30 years, during which its obsequies have been frequently celebrated with even greater gusto than Dr. Joussett devotes to them. Of serotherapy he is more hopeful, and he discusses this line of treatment at considerable length. Both volumes contain a mass of useful information presented in a highly readable and assimilable form.

2. *A Study in the Epidemiology of Tuberculosis.* By GEORGE E. BUSHNELL, Ph.D., M.D. London: John Bale, Sons, and Danielsson. 1920. Pp. 221. 20*s*.

Colonel Bushnell, who is Honorary Vice-President and Director of the National Tuberculosis Association of the U.S.A., calls this book a study of the epidemiology of tuberculosis. As such it is remarkably incomplete. Many and important epidemiological aspects of tuberculosis are totally ignored or only briefly referred to. But as a study of one aspect of the problem this book is of great value, because, in his advocacy of only one school of thought, the author has collected most of the available evidence supporting this school and has moulded it into a very convincing thesis. With engaging frankness he confesses that his views, as set forth in this book, are not supported by any original investigations. His aim has been rather to collect and discuss epidemiological data which have hitherto been buried away in inaccessible journals written in foreign tongues. Copious extracts from papers, mostly German, have been made, and it is evident that Dr. Bushnell's views are largely the expression of the teachings of Römer and others.

The gist of his message is that the first infection more or less decides the subsequent fate of the patient, whose susceptibility to reinfection from without is no greater than that of a syphilitic to reinfection with syphilis. "There is no good reason why disease caused by the virulent and highly resistant tubercle bacillus should form an exception to the law that reinfections do not take place so long as the infectious agent is present." The author goes on to show that, while the *mortality* from tuberculosis rises and falls with the general mortality and environment, there is practically no change in its *morbidity*. The author stamps as "the error of modern times" the denial of the teaching that a first infection prevents renewed infection from without. But once this elementary hypothesis is used as a key to he seemingly complex problems of tuberculosis "the riddle of the centuries" is solved. To readers intrigued by the notion that consumption can be eradicated by a wholesale roping in of sputum-positive cases in segregaion camps it must seem rank heresy when the author writes "...... the consumptive, much to be dreaded is at close quarters for the uninfected, is indispensable in the present era because he unwittingly provides for that immunisation which prevents our race from perishing, as so many other races have perished when thrust unprepared into the midst of infection." This book is to a great extent an exposition of Römer's law, according to which tuberculosis runs an acute and fatal course in communities where it is rare, and a chronic and relatively benign course where the disease is common. Or, that contact with tuberculosis affords a certain protection against it.

After reviewing the literature dealing with tuberculosis in highly civilised and primitive races, and the invaluable evidence provided by v. Pirquet's test, the author shows with convincing logic that the solution of the problem is to be found in the conditions under which infection first occurs. In civilised communities the problem is thus referred to very young children. If these can be protected against a large initial infection an all-important step has been taken. He quotes Pollak of Vienna as showing that after the age of 4 children do not appear to be unfavourably affected by the entrance of a tuberculous individual into the family circle, while those of lesser years grow up more delicate. When a child has recently become infected, as shown by v. Pirquet's test, the greatest possible care should be taken of it "to the end that the infection may remain latent." There can be no doubt, the author argues, that the first half-year after infection is a critical time for the child. "Proper attention at this time would do more to lower the morbidity and mortality from tuberculosis than anything except preventing the infant from coming into contact with the consumptive." The author's views on bovine infection are summed up in the following: "It is an Utopian dream ...... to hope that the tuberculous infection of cattle will ever be totally eradicated. But if this is not done, given the disappearance of the typus humanus, immediately bovine tuberculosis rears its horrid head, probably as formidable a menace as tuberculosis of the human type has ever been!." Being convinced that we must live with the tubercle bacillus if we are to enjoy the benefits of tuberculisation, the author regards a "sterilisatio magna" as little short of disastrous, and the ultimate object of his ambition is the replacement of nature's methods of tuberculisation, so terribly wasteful of human life, by a thoroughly scientific method of artificial inoculation which need sacrifice no life. Whether Colonel Bushnell has actually solved "the riddle of the centuries" or not, he has at least put forward many cogent arguments in favour of an hypothesis which, if it prove correct, would greatly simplify the campaign against tuberculosis.

3. *The Early Diagnosis of Tubercle.* Third edition. By CLIVE RIVIERE, M.D., F.R.C.P. London: Henry Frowde, Hodder and Stoughton. Oxford Medical Publications. 1921. Pp. 318. 15*s*.

BARELY two years have elapsed since the publication of the second edition of this useful book, and little alteration has been made in the present edition. In the section dealing with the differential diagnosis of tubercle, an important improvement has been made by the inclusion of pulmonary syphilis as one of the conditions which may simulate tuberculosis of the lungs. The author does not consider syphilis a very common simulant of pulmonary tubercle, and he quotes McCrae and Funk as finding only four cases of pulmonary syphilis among 1200 cases at the Jefferson Chest Hospital. On the other hand, the author admits that syphilitic ulceration of the trachea and bronchi may be comparatively common and may give rise to signs, such as cough and dyspnœa, suggestive of various diseases other than syphilis. Discussing the differential tests, he puts the therapeutic test last, but he admits that the best evidence of a syphilitic lesion lies in its response to antisyphilitic treatment. Mercury he recommends with confidence, but the iodides he advocates with the reservation that they are apt to cause a congestive reaction in active tuberculous lesions. Another condition which he introduces for the first time into his discussion of the differential diagnosis is pneumo-mycosis. In other respects, this third edition differs from the second chiefly in those finishing touches which every conscientious author wishes to add almost before his book has emerged from the press. With the recent, rather melodramatic exposures of incorrect diagnoses of tubercle, the need for an authoritative work on the early diagnosis of tubercle has become more than ever evident, and the author is to be congratulated on the lucid and comprehensive manner in which he has tackled a very difficult task. In the matter of percussion he is at his best—a best which leaves the possessor of an ordinary pair of hands humbly conscious of his deficiencies. We disagree with the author's aphorism that "where the teachers are at variance the tree of knowledge can hardly be expected to flourish." Discussion leads to truth, while untested views lead to dogmatism.

---

4. *Die Lungentuberkulose.* Ihre Pathogenese, Diagnostik, und Behandlung. By Professor FELIX KLEMPERER. Berlin: Urban und Schwarzenberg. 1920. Mit 16 Textabbildungen und 5 Tafeln. Pp. 164. M.40.

WHEN an author in the preface to his book announces that it is intended not for students but for practitioners, he raises hopes that the jog-trot platitudes of orthodoxy will be abandoned in favour of a free exploration and discussion of new ideas and possibilities. In this case such hopes are, indeed, ultimately fulfilled, but before he is admitted to the author's own sanctum the reader must submit to a novitiate, during which he is regaled with such pabulum as: "The cause of pulmonary tuberculosis, as of every other form of tuberculosis, is Koch's bacillus." When he passes from such established facts to matters still in dispute the author's attitude is guarded and judicial; to the question whether pulmonary tuberculosis in the adult is due to endogenous infection resulting from disease in childhood or a new infection from without, he gives the safe, but not helpful, answer that both hypotheses may tally with the facts. Tuberculin treatment, he maintains, is to-day the "most important ætiological specific method of treating pulmonary tuberculosis." A few pages further on, and after a critical review of the literature of tuberculin therapy, he admits that tuberculin is "a useful support to general treatment, not more and not less." He is more emphatic on the subject of protein therapy, and he finds injections of milk, so vigorously puffed of late in certain quarters, as quite unsuited to replace tuberculin. His experiences of "partigen" treatment on Deycke-Much lines have left him unconverted. As for treatment with live cultures of acid-fast microbes, he has little hope to offer; he has given Friedmann's cultures in 40 cases, but even when the pulmonary disease was taken early, no marked benefit ensued from this treatment. In a short review of pneumothorax treatment the author opines that every operation fatality can be traced to air embolism, and that pleural reflex accounts only for some of the alarming symptoms not terminating fatally. Useful notes are appended to the symptomatic treatment of such trying complications as night sweats and cough.

---

5. *Die specifische Percutanbehandlung der Tuberkulose mit dem Petruschkyschen Tuberkulinliniment.* By Dr. F. GROSSMANN. Berlin: Urban und Schwarzenberg. 1921. Pp. 76. M.12.

Dr. Grossmann throws into this booklet on the treatment of tuberculosis by innuction with Petruschky's liniment all the fervour that personal recovery under specific treatment is calculated to infuse. After undergoing Petruschky's treatment the author has, in conjunction with Petruschky, done much to put this treatment on a rational and systematic footing. Readers with a lurking suspicion that this method represents an inert, harmless placebo will note that the author finds it contra-indicated in the presence of high fever, mixed infections, and other debilitating conditions.

A PHYSICIAN'S ANTHOLOGY OF ENGLISH AND AMERICAN POETRY.

Selected and arranged by CASEY A. WOOD, M.D., and FIELDING H. GARRISON, M.D. London: Oxford University Press. 1921. Pp. 346. 8*s.* 6*d.*

THE appearance of another anthology requires justification, because if it is to be representative it must contain verses which have been published repeatedly in different forms. "A Physician's Anthology of English and American Poetry" has the best and most logical of origins; it was intended as a birthday offering on his seventieth birthday to Sir William Osler, "le physicien, le plus poéte que jamais," to paraphrase Liszt's description of Schubert. The prophet of international medicine did not live to see the book published, but the scheme and much of the contents had already passed through his hands, and he had given his approval. It is to his memory therefore that the volume is dedicated. The book is not a collection of verses by medical men, nor do the poems deal with medical subjects. It is, says Dr. Garrison in his foreword, difficult for a physician to find time and energy to read poetry; and it is this, and not lack of appreciation which deters them. The arrangement of this collection is intended to facilitate reading for these time-pressed doctors of medicine.

The volume is divided into 18 sections from "Youth and Manhood" to "Divina Mors," passing through such experiences as "Nympholeptos" and "Taedium Vitae," and the poems are chosen very widely. Thus we find in the anthology, under the heading "Amantium Irae," Shakespeare's "Let me not to the marriage of true minds" facing Rupert Brooke's "The Hill." And under the section "In War Time" Milton's "*Captain or Colonel or Knight in Arms*" precedes Walt Whitman's wonderful pictures of the American Civil War, and is followed by a chorus from "Prometheus Unbound" and Dr. Henry Head's dignified and pathetic message to those who in the recent war were found too old to fight. Here also is Mr. Siegfried Sassoon's mordant estimate of a certain sort of blatancy, that was neither so useless to the Allied cause or so wholly hoggish in its origins as he thinks, but which certainly gave a chance of expression to very unworthy sides of character and conduct.

Anthologies remind us of the time-saving, trouble-saving doctrines of modern life, from which now apparently even the reading of poetry may not be excluded; but they lead to a wider appreciation of the English-speaking poets and as such are heartily welcome. The class of readers aimed at in this collection will find that an excellent choice has been made for them.

POVERTY AND ITS VICIOUS CIRCLES.

Second and enlarged edition. By JAMIESON B. HURRY, M.A., M.D. London: J. and A. Churchill. 1921. With illustrative diagrams. Pp. 411. 15*s.*

THOSE who are taking up social work will read with interest and profit this second edition of Dr. Hurry's work. As the author says in his preface, "Social reform has received an impetus which shows no signs of slackening and whose effects are reaching to the remotest quarters of the earth."

Part I. of the book deals in 22 chapters with the vicious circles of poverty. Part II. shows how as the effect of these vicious circles poverty becomes a self-perpetuating, a self-aggravating, and a fatal disorder. Part III. deals with the attempt to break the vicious circles by legislation, by the work of voluntary organisations, and by individual effort. In the conclusion (Part IV.) the author discusses the methods which promise most success in the future.

There are interesting accounts of the extension of the franchise, of social legislation, of the Elberfeld system, of the Poor-law, and many other matters. The author has more faith in legislation than in the Poor-law. He gives special praise to the friendly societies and the coöperative movement. We are not sure, however, that coöperators are always model employers. Dr. Hurry says (p. 134) that the diminution in lunacy among females during the war, in spite of the emotional wave pervading the nation, "was due to the full occupation of, and high wages paid to, all women who could work." This statement is specially interesting in view of the large proportion of domestic servants and of governesses among the older female patients in county asylums, both being occupations formerly badly paid and allowing of small emotional outlet. Trade-unions come in for some criticism from Dr. Hurry for the narrowness of their outlook and "a certain lamentable selfishness of purpose." It has certainly been extraordinary how little the keen male trade-unionist has interested himself until quite recently in the organisation of woman's labour. The man who has worked hard for due recognition of the value of his own labour has allowed his wife or daughter to work for "pocket money" wages, and has, as Dr. Hurry points out in Chapter 16, thus helped ultimately to reduce his own wages. We note that in the chapters on defective feeding and wastefulness the author retains the idea that one protein is as good as another and that margarine is equal to butter. We think, in view of recent work on amino-acids and vitamines, such statements should be qualified.

The book is written rather in a philosophical than in a practical spirit. The author has no new remedies to put forward and does not even discuss proposals such as pensions for mothers or State subventions for the relief of poverty of the widow with young children or of the large family of the man earning a labourer's wage. In his conclusion he professes himself an optimist, but perusal of his book left us in no such frame of mind. The devotion of a separate chapter to each circle, while it leads to inevitable repetition, makes it difficult for the reader to formulate from the whole a practical programme of social reform.

STUDIES IN DREAMS.

By MARY ARNOLD-FORSTER. With a Foreword by Dr. MORTON PRINCE. London: George Allen and Unwin, Ltd. 1920. Pp. 186. 8*s*. 6*d*.

THE reader who is familiar with the recent literature of dream-study and cognate topics may find himself attracted by this book because of its literary qualities rather than by any new knowledge about dreams which it may provide. For Mrs. Arnold-Forster's style is a welcome change from the kind of writing to which we are accustomed in "scientific" accounts of the nature of dreams; and her sane and dispassionate consideration of the problems presented by her own dream-life is a model which more dogmatic writers might do well to copy. Mrs. Arnold-Forster approaches the subject with the intention of finding out by observation and experiment what can be learnt about the working of the various mental faculties in the dream-state; and she discusses the part played by the will, reason, imagination, and memory. Her own experience of the possibility of controlling her dreams leads her to believe that "the dream mind is far less independent of our will than is supposed, and that, to a degree that is not generally thought possible, the waking mind can, and does, direct the activities of the mind in sleep." The examples adduced in support of this opinion are strongly reminiscent of the influence of suggestion in suggestible or hypnotised subjects, and since we know that in such subjects dreams can be imposed on the dreamer's mind and their course determined by suggestion from without, there is no reason to doubt that self-suggestion may, in some cases, be equally efficacious. In this sense voluntary dreaming and "dream control" may be possible; but this is not to say that the will is active *during* the dream.

Great importance is ascribed to the part played by sensory impressions during sleep, and to their power of arousing memories with hallucinatory vividness. In dreaming, association of ideas is assumed to be free from all inhibitions, and as soon as a thought arises in the mind its sensory imagery takes *concrete form* and appears as objective reality. The dream is fashioned from such sources entirely, and its structure and course unted for by the free play of association and a tening of the faculty of imagination." No attempt is made to discover why the flights of imagination take the course they do; they are obviously regarded as the product of "free" fancy. Thus the dream, having no *meaning*, needs no "interpretation." In her dislike of the symbolic interpretations made use of in psycho-analysis the author seems to have forgotten the importance of the method of dream interpretation by "free association," though without investigation by this method the personal significance of any dream is elusive. A striking feature of the author's own dreams is their coherence into connected stories. As Dr. Prince points out in his foreword, "the dream-mind, like all dissociated systems, can be educated into a highly organised intelligence." This appears to have been the case with the dream-mind of the author, and when this happens, the dream-life assumes a very different character from that which it shows in ordinary people.

Interesting accounts of dreams which show some amount of supernormal faculty, and descriptions of experiences in the borderland state between sleep and waking occupy a considerable part of the book. In a future edition more care should be taken in proof-reading. On page 159 Professor McDougall's name appears three times as "McDowell."

PRÉCIS DE MICROBIOLOGIE CLINIQUE.

Par FERNAND BEZANÇON. Paris: Masson et Cie. 1920. Pp. 600. Fr.30.

THIS book is one of an admirable series of volumes, the "Collection de Précis Médicaux," issued by Masson et Cie. The present edition is the third, and maintains the form and scope of the previous ones. There are naturally certain additions and extensions corresponding to the growth of knowledge or to the added importance of certain branches of bacteriology. Thus the methods of bacteriological diagnosis of cerebro-spinal meningitis, of typhoid and paratyphoid, and of dysentery are discussed at length and in detail. The information contained in the book, though stated to be elementary, is abundant enough to supply interesting reading to experts, and is given with the precision common in French authors. The book can be confidently recommended to laboratory workers and to clinicians.

MANUAL FOR HEALTH VISITORS AND INFANT WELFARE WORKERS.

By Several Writers. Edited by Mrs. ENID EVE, late Ministry of Health; formerly Chief Health Visitor and Sanitary Inspector to the Borough of Holborn. London: John Bale, Sons, and Danielsson, Ltd. 1921. Pp. 194. 10*s*. 6*d*.

THIS little book is one of a series of modern clinic manuals. Dr. Bostock Hill writes a preface, and we cordially agree with his views as to the desirability of a conjoint appointment of so-called health visitor, school nurse, tuberculosis visitor, and midwife inspector, wherever this is at all possible. From the point of view of the health visitor her work should be varied; from the point of view of the work overlapping should be avoided, and the mother in the home should not be worried by all kinds of different official visitors, but should be visited by one woman who can try to constitute herself the friendly adviser of the family in health matters.

The book, as might be expected from the experience of the editor, who is also the author of many of the chapters, is full of good sound advice to those who are contemplating the adoption of the career of health visitor. Apart from training, the great requisites of a health visitor are tact and good temper. The advice in this book ought to help in the acquisition of tact and in the assumption of the virtue of good temper even by those who have it not. The booklet contains a useful appendix with regard to training institutions and curricula for health visitors, and it is unfortunate that its price may possibly prevent it from coming within the reach of all health visitors. Health authorities might save public money by presenting it where it would be useful and used.

THE LANCET.

LONDON: SATURDAY, MARCH 26, 1921.

Ophthalmia Neonatorum.

OPHTHALMIA neonatorum has been notifiable since April 1st, 1914, and in some recently issued reports of medical officers of health reference has been made to its increased prevalence. Ophthalmic surgeons are agreed that with proper treatment of the eyes at birth the disease can be prevented, and cases of it should become exceedingly rare. There is general agreement that when it has occurred, given adequate and prompt treatment, damage to either eye should be very exceptional, and the loss of an eye almost unknown. In these circumstances the occurrence of a case in any lying-in hospital should be made the subject of careful inquiry. Obstetricians and gynæcologists are not eye specialists, and it follows that every lying-in hospital should have a call on the services not only of a physician interested in pædiatrics, but also of an ophthalmic surgeon, so that the nursing staff, the pupil midwives, and, last but not least, any students attending the practice of the hospital, may have adequate instruction in the methods necessary to prevent the disease. If the first line of defence against ophthalmia is broken, efficient curative methods would thus be applied at the earliest possible moment.

From two-thirds to three-quarters of the births in the country being attended by midwives, the Central Midwives Board should see to it that registered midwives receive the necessary instruction in the use of one of the silver solutions recognised as being effective. Local authorities are empowered to issue these solutions to midwives capable of using them. It should not, however, be hastily assumed that births attended by midwives involve the greatest danger. Recently we heard of a case where it was intended to make all possible provision against unforeseen circumstances. The family medical attendant, a consultant obstetrician, and an experienced monthly nurse were all three engaged beforehand. Attention was concentrated on the mother: the baby lost one of its eyes. The midwife is bound by the rules of the Board to send for medical help whenever there is "inflammation of, or discharge from, the eyes, however slight," and to notify the medical officer of health that she has done so. Thus, when a midwife attends a birth, provision is made for very early notification of ophthalmia neonatorum. The medical attendant does not wash the baby and may fail to notice the first signs of anything wrong with its eyes. When a case of ophthalmia does occur it is not sufficient for the midwife to send for the nearest doctor. Many practitioners make no claim to special knowledge of eye diseases, and one who rarely meets with such cases might not recognise at once that he is confronted with something formidable. Valuable time may be wasted in ineffective treatment with boric lotion, and irretrievable damage may be done before the case comes to the notice of an ophthalmic surgeon. In face of the menace of such a tragedy as a blind child we must not stand on ceremony or take risks. The medical officer of health, who finds that treatment is not being effectively carried out, ought to be able to arrange with the general practitioner to have mother and child removed to hospital at once—the mother in order to prevent weaning and also that her own treatment may be undertaken if the disease is gonorrhœal in origin. In every large centre of population beds should be available for this purpose, whether in a municipal or a voluntarily supported hospital. The stay in hospital is short and the expense slight compared with the importance of the object in view. From one-quarter to one-third of the inmates of institutions for the blind are there on account of inadequately treated ophthalmia neonatorum. We must cut off this supply of human misery at its source.

In the Memorandum of the Ministry of Health dealing with the form of annual report for 1920 it is laid down that "details should be given of each case of ophthalmia notified, showing whether one or both of the eyes suffered permanent injury, and if so, to what extent." Such annual reports hitherto have not given this information, but have simply returned the number of cases notified. Special forms are now issued by the Ministry which are to be filled in for notified cases of encephalitis lethargica, acute poliomyelitis, and cerebro-spinal fever. This is done for the purpose of increasing our knowledge of the diseases mentioned. We suggest that special forms should be issued by the Ministry to be filled in for each case of ophthalmia neonatorum, in order that we may know what damage is done by this disease and to what extent the knowledge of it we actually possess is utilised or ignored. By the adoption of such a plan attention would become focussed; the occurrence of cases of ophthalmia neonatorum would be enormously decreased and the loss of eyesight from this cause would practically disappear.

◆

Protozoal Intestinal Infection at Home.

INVESTIGATIONS on the human intestinal protozoa were undertaken during the war with the object of clearing up the diagnosis in thousands of cases of dysentery and other intestinal disorders. The patients were continually invalided home from the near and far East, and very soon the fact was brought to light that *Entamœba histolytica* and other protozoa were often present in cases which had had no dysentery, nor, indeed, any intestinal malady whatever. It became clear, therefore, that it was only a small percentage of those actually infected with *E. histolytica* which acquired true dysentery. As a few isolated cases of dysentery and liver abscess and one carrier case had been recorded as occurring in individuals who had never left the British Isles, the suspicion was aroused that infection with *E. histolytica* amongst the inhabitants of Britain might not be so rare as was generally supposed. With this idea in mind, and assisted by several trained experts working in different parts of the country, Mr. CLIFFORD DOBELL, on behalf of the War Office Committee on Dysentery, of which he was a member, organised an investigation of the indigenous population. A similar investigation had already been undertaken at the Liverpool School of Tropical Medicine. present Report,[1] which is not the least of the many valuable publications emanating from the Medical Research Council, contains a critical review by Mr. DOBELL of the records and results of the various investigations just mentioned, together with an account of cases of *E. histolytica* infection previously recorded amongst residents of the British Isles.

---

[1] A Report on the Occurrence of Intestinal Protozoa
tants of Britain with special reference to *Entamo*
By Clifford Dobell, F.R.S. (Protistologist to the M.
Council), with contributions by A. H. Campbell, B
D.Sc., R. C. McLean, M.A., Muriel M. Nutt, ac
A.R.C.S. Medical Research Council, Special
1921. Price 2s. net.

The investigations extended over a large class of population, the Liverpool examinations including civilians in Liverpool Royal Infirmary, army recruits, children, asylum patients, and university and school cadets. Other reports deal chiefly with the artisan class of Birmingham, Brighton, Leeds, Sheffield, Bristol, and Reading. As a result of these examinations it was found that the following protozoa were present, the figures representing the incidence percentage amongst over 3000 individuals examined: *E. histolytica* (7–10), *E. coli* (35–54), *E. nana* (9–13), *Iodamœba bütschlii* (0·5–0·75), *Giardia intestinalis* (18–27), *Chilomastix mesnili* (6–9). It was thus demonstrated that the working-class population examined was infected with *E. histolytica* to the extent of 7–10 per cent. The earliest age at which an infection with this organism was found was three years, but that it may be expected at an earlier age is demonstrated by the finding of *Giardia intestinalis* in a child of 3 weeks. Sex does not influence the chances of infection to any extent, nor does occupation, with the exception of that of miners, who provided the greatest number of infected individuals. Certain instances of family infection came to light, and one is mentioned in which the father and mother and five of six children were all infected with *E. hystolytica*. It thus appears that practically all the common intestinal protozoa of man occur indigenously in all parts of Britain, and, as the writer remarks, it is no longer necessary to seek a foreign origin for every case of protozoal infection found in this country. Attention is also drawn to observations which indicate a similar state of affairs in France, Holland, and Germany.

All evidence goes to show that these infections are not a result of the war, and there is every reason to suppose that they have existed amongst the population for hundreds of years. The figures indicate the frequency with which inhabitants of our islands consume food and drink which has been exposed to gross contamination with fresh human fæces. The fact that so large a percentage of the population is infected with *E. histolytica* does not mean, however, that many cases of amœbic dysentery will occur. Compared with the number infected those who acquired the disease are actually very few, and the more frequent occurrence of amœbic dysentery in tropical countries is accounted for by the much higher incidence of infection. The presence of *E. histolytica* in the population of Britain need not be regarded with alarm. Nevertheless, in the future as in the past, this protozoa may be expected to cause some cases of dysentery and liver abscess, and because of the serious nature of these diseases its presence should be recognised by medical practitioners and the possibility of its occurrence in certain cases duly considered. Protozoal infections of the human intestine can no longer be regarded as peculiar to the tropics. They are generally more frequent there, because it is in those regions that sanitation is relatively defective. That they occur to the extent they do in Britain is perhaps surprising; [illegible]w, it is a fact well worth the attention of sani[illegible]ns. May not the incidence of protozoal infections be an index of the efficiency of sanitary systems and personal hygiene amongst any given population? The facts brought out so clearly in this most interesting Report deserve attention commensurate with their far-reaching importance.

Approved Societies and Voluntary Hospitals.

DURING the debates at the end of last year, by a Standing Committee of the House of Commons, upon the Ministry of Health (Miscellaneous Provisions) Bill—a measure which was afterwards rejected by the House of Lords—the most important discussion from the medical point of view centred round Clause 11 of the Bill, which sought "to give power to county councils to supply and maintain hospitals, to contribute to any voluntary hospitals within their area, to undertake maintenance of Poor-law hospitals and institutions, and to establish and maintain or contribute towards the ambulance service." In view of representations that this clause, by setting State organisation at rivalry with charity, would prejudice the voluntary system of hospital support at a critical time, and just when there was a strong feeling that the country did not enjoy to the full the benefits that might be obtained under that system, Dr. ADDISON stated that he would forthwith appoint a committee "to inquire into and report upon the financial position of the voluntary hospitals throughout the country." This was a wise move, for until accurate information was made public from authoritative sources the most widely differing estimates as to the poverty of the voluntary hospitals had to be dealt with as serious, even though, if some of the statements were true, others must be false.

The Committee appointed by Dr. ADDISON consisted, as he promised it should, of five Members only, none of them being medical men or connected with hospital arrangements in any way, and from this small and impartial body, over which Lord CAVE presided, expeditious advice has now come in the form of an Interim Report.[1] The document, which is unanimous, commences by acknowledging that from evidence received the conviction has been reached that it is desirable in the public interest to maintain the voluntary system of hospital management, and we are glad to welcome a pronouncement which we anticipated. The Committee find that the present situation of financial depression has been mainly due to the large increase, during and since the war, of salaries and wages, and in the cost of provisions and materials; and they hope later to make recommendations as to the practical methods of remedy. But in the meantime an Interim Report is issued because a pressing matter, whose consideration is within the terms of reference, has just presented itself. The quinquennial valuation of Approved Societies under the National Health Insurance Acts shows a considerable surplus over the amounts required for the purposes of the Acts. "Excluding Ireland," says the Report, "the valuation of 4926 societies and branches containing 2,558,123 members (out of a total of approximately 10,000 societies and branches containing nearly 15,000,000 members) which had been completed on Dec. 24th last, showed a total disposable surplus as at Dec. 31st, 1918, of £2,171,576, and it is anticipated that when the valuation is completed the total disposable surplus of all the Approved Societies will not be less than £7,000,000. This result is attributed to a material extent to conditions arising out of the war, such as the reduction owing to war conditions of sickness, disablement, and maternity claims, and the release of reserves in respect of members killed on active service." Now under the provisions of the Acts the Approved Societies may, during the next five years and with the approval of the Ministry of Health, utilise any surplus at their disposal in providing additional sick benefits, while the payment of the whole or any part of the cost of the maintenance and treatment of members in a hospital or convalescent home is specifically mentioned in the list of additional benefits authorised by the Acts. The strong opinion of the Voluntary Hospitals Committee is that, in the interest both of the hospitals and of the Approved Societies, a substantial part of the disposable surplus should be applied towards the cost of the maintenance of members of the Societies while they are in hospital. We believe that the larger of the Approved Societies will find themselves in full accord with the suggestion of the Voluntary Hospitals Committee. Those who desire to maintain the voluntary system—even its most ardent supporters—have never disguised from themselves that that system requires much strengthening. How could any other view be held having regard to the statements of their pecuniary plight which continue to emanate from all parts of the country and from some of the best-known institutions? But it has been clear for a long time that the country does not reap to the full the benefits that might accrue under the voluntary system, because of the ineffective procedure which characterises much of the administration. Subscriptions are not collected in any systematic manner from large classes who are quite able to assist. The three outstanding sources for an increased hospital revenue under the voluntary system have been seen to be, first, large business firms whose employees receive benefits in many cases out of all proportion to any donations or subscriptions made by the firm; secondly, the patients themselves, a very large proportion of whom are able to pay something towards their maintenance, although unable to meet the great cost of long illnesses, operative interference, or special treatment in their own homes; and thirdly, the Approved Societies, to whose members the work of the voluntary hospitals is of very great value. The Interim Report states that of the patients treated at the hospitals "a considerable portion, about 30 per cent. of the out-patients, and a larger percentage of the in-patients, are insured persons, and the effect of hospital treatment is not only to relieve these patients from suffering, but also to reduce the period during which they are a charge upon the Insurance funds." If the war, while depleting hospital funds, has had the effect of greatly increasing the surplus available to Approved Societies a special reason is provided for the consideration by the Societies of the claims of the hospitals.

---

[1] Ministry of Health, Voluntary Hospitals Committee: Interim Report. London: H.M. Stationery Office. (Cmd. 1206.) 1*d*. net.

The Report concludes by recommending succinctly to the Ministry of Health that the matter should be brought to the notice of the Societies concerned, who should be advised as to the amount of the contributions which could reasonably be made out of their available surplus. The urgency of the situation, which has led to the issue of an interim document, is due to the occupation at the present time by the Societies in framing schemes for the future. Obviously, it would have been more convenient to include in a general report the consideration of the responsibilities of the Approved Societies towards the hospitals, when the relation of these circumstances to the whole complex problem would have been apparent. But, in the circumstances, it became necessary for the Committee to call the attention of the Ministry to the inadvisability of approving of any scheme for the disposal of the Societies' surplus until their recommendations on the subject had received consideration.

◆

A DEFENCE OF THE MEDICINE-MAN.

DR. MARETT, reader in social anthropology at the University of Oxford, is one of the latest apologists of medical ethics, as they were understood by our remotest ancestors. In a chapter on The Primitive Medicine-man in his "Psychology and Folk-lore," published in 1919, he takes up the cudgels for a class which has pretty generally been regarded hitherto as composed almost entirely of quacks and deliberate swindlers. According to him the medicine-man of antiquity, as well as his tribal representative to-day, was, and is, no humbug. The Australian aboriginal practitioner believes as firmly as his patient that disease, especially if it be sudden in its onset and obscure in its origin, has been caused by the introduction into his patient's head of some foreign body—usually a piece of crystal—and this he proceeds to extract symbolically. After uttering the proper prayers or incantations he apparently brings a piece of crystal out of the cranium of the sufferer, but—and this is the point to remember—he does not seek to hoodwink anyone by what appears to be a sleight-of-hand trick. His patient and his patient's friends are not for a moment deceived by him. They know as well as he that he has been holding the piece of crystal in his hand—or up his sleeve, if he wears one—and that he has only acted ritualistically throughout. The crystal is a symbol of the mischief within the head, which may in its turn for the matter of that be only referred to as a crystal *pro formâ*. What the medicine-man really does is to set the good magic influence or "nama" within himself to combat the bad "nama" afflicting his patient. He, in fact, deals in the occult, but he does so with high moral intent, and has attained to the power of so dealing only after severe training, involving fasting, isolation, and all the other miseries of a special initiation.

DR. MARETT'S contention is engaging and it makes for the honour of the profession that at present represents the tribal medicine-man, the tribal king, priest, and bard, for there was an early period in human history when all these offices or functions were perhaps often combined in one person. Whether, however, his theory can be said to hold true in all cases is another question. Probably there were good medicine-men and bad, from the latter the charlatans being descended. Something very like "nama" still lingers in the prescriptions of illicit practitioners, and many primitive people in every class all the world over are attracted by the occult element in a patent pill. Dr. MARETT recognises the fact that among primitives malpractitioners were not unknown, but he is careful to show that the good medicine-man, who views his craft in the light of a religion, is always anxious to drive out mere magicians and necromancers from the circle of the profession. Practice involves high moral standards and an ascetic outlook on life. It was an Australian aboriginal who told Dr. HOWITT that he had taken to drink, and that as a consequence the virtue had gone out of him. We trust that he was quite sincere in his professions, since a sceptic might argue that the savage is always anxious to stand well with those strange white men of the missionary type, with their new-fangled views about temperance and continence, and their undoubted supplies of beads, blankets, and other good things.

Annotations.

"Ne quid nimis."

UNIVERSITY GRANTS.

THE Universities Grants Committee have just issued their report, which they describe as a preliminary survey of some of the outstanding difficulties of finance and organisation which confront the universities at the present time. The Committee consist of Sir William M'Cormick (Chairman), Dr. W. Bateson, Sir Dugald Clerk, Sir J. J. Dobbie, Miss S. M. Fry, Sir F. G. Kenyon, Sir Stanley Leathes, Sir Wilmot Herringham (who was appointed in place of the late Sir William Osler), and Sir J. J. Thomson. The report opens with an expression of the Committee's sense of the efficiency maintained in the universities and colleges generally in the face of serious difficulties; the members were convinced at an early stage in their investigations that the present resources of the universities are inadequate. Since the armistice the Treasury grants as a whole have been increased by 83 per cent., and support has been obtained through increased tuition fees, and, in some instances, assistance from local education authorities; but all expenditure has increased enormously, and even if pre-war incomes had been doubled it is doubtful whether the universities would be as well off as they were before the war. The Committee are satisfied that the efficiency of university education will be seriously endangered unless further substantial improvement is made in the salaries of teaching staffs. It was clear from evidence received that some members of university staffs were living in circumstances quite incompatible with continued efficiency; material readjustments of salaries were long overdue in 1914, and present economic conditions emphasise the urgency of the question. The Committee doubt whether universal flat rates and automatic increments are possible or desirable, but they consider that it would be an advantage if all grant-aided institutions could agree upon basic minimum salaries within grades and faculties. Hardly less important is the provision of a suitable system of superannuation, with maintenance of the autonomy of the universities, and facility for free transference of teachers into other professions. The insufficient numbers of teachers are also causing anxiety to university authorities; members of the staffs are, as a rule, not only underpaid but also overworked, and sufficient leisure to pursue research is as essential as adequate remuneration. With reference to tenure of appointments the Committee are of opinion that greater fixity is in many cases desirable; and as regards status, lecturers below the rank of professor should be given an effective voice in internal administration and the regulation of study and discipline. Passing on to the subjects of equipment and accommodation, the Committee refer to the necessity of adequate provision for increase and upkeep of university libraries, and to the wider recognition of the importance of the librarian's position. The needs of the Faculty of Arts are mainly for personnel; the Faculty of Pure Science requires, in addition, accommodation and material equipment, particularly in view of the large numbers of ex-Service students who have recently entered the latter department of study.

Turning to applied science, the Committee take the Faculty of Medicine as the best example of the theoretical and practical in combination, as the requisite thorough grounding in the basic sciences of physics, chemistry, and biology, and in the intermediate anatomy and physiology, illustrate the essential condition of a university education in any applied subject. The Committee are of opinion that no education can be called liberal which leaves a student at 18 ignorant of the fundamental laws of nature; but there are too few secondary schools in which these subjects are at present properly taught to permit the universities to dispense with elementary instruction them. Within the past 25 years the teaching of students of medicine has been very widely extended, and is now passing into the hands of teachers devoting their entire time to the work, each subject of which requires much space and great expense for laboratory purposes. It has not in England been considered a necessary qualification for teaching medicine that a man should have practised laboratory methods of advancing the science; the Royal Commission of University Education in London, reporting in 1913, recommended the setting up of a system which would provide teachers and assistant staffs willing to devote themselves to scientific investigation. This system is now in operation by means of the clinical units established, with the assistance of grant aid from the Treasury, at the medical schools of four London hospitals, and the Committee state that everywhere throughout England and Scotland the principle has been seized upon and the need realised; they have issued a statement for the guidance of university bodies contemplating the establishment of new arrangements to this end.

In considering general needs, the Committee recommend throughout the provision of grant aid in the form of block grants. Reference is made in the report to the serious shortage of residential accommodation for students in most of the great cities, and to the wide extension of extra-mural work. In consultation with the authorities of universities and colleges the Committee have drawn up for annual presentation to Parliament schedules displaying the essential items of income and expenditure, together with statistics of students. They express the opinion that it is not perhaps an impossible ideal to look forward to a general scheme whereby the areas served by different universities should be defined, and all rating authorities should contribute to their local university the proceeds of a penny rate. In conclusion, the Committee emphasise the possibility of local support in future grant allocations, and urge upon university authorities the importance of regarding their endowment funds as their central source of revenue.

ACUTE PERITONITIS SIMULATING ENTERITIS.

CONSTIPATION is the rule in acute peritonitis and in the cases in which diarrhœa occurs the peritoneal symptoms—abdominal pain and tenderness and repeated vomiting—generally render the diagnosis clear. At a meeting of the Société Médicale des Hôpitaux of Paris, MM. A. Bergé and J. Roberti reported a case in which the diarrhœa was so prominent a symptom and the signs of peritonitis so slight that the diagnosis from acute enteritis remained doubtful for a long time and prevented operation at the most favourable time. A dressmaker, aged 21 years, was admitted into hospital on July 23rd, 1920. The history was that after dancing all night on the 17th and taking six or seven ices she had slight rigors on the evening of the 18th. However, she was able to work on the 19th. That night she was attacked with diarrhœa and pain in the abdomen, which from the first was generalised. On the morning of the 20th she vomited her coffee. The diarrhœa, accompanied by colic, continued. Fifteen to 20 greenish glairy stools were passed daily. For five months she had suffered from leucorrhœa. Menstruation was very irregular. On examination she was prostrate, and the eyes were sunken. More than 10 greenish glairy fœtid stools had been passed in 12 hours and one contained a little blood. There was no nausea. In the hospital she vomited three-quarters of a litre of greenish fluid; this was the second time she vomited in four days. The abdomen was a little distended, tender all over, and especially in the left iliac fossa. But the tenderness was neither exquisite nor superficial; strong pressure was necessary to provoke it. There was no cutaneous hyperæsthesia and no pain on sudden depression of the abdominal wall. The patient could sit up without pain. The tongue was moist, the temperature 102·8° F., the pulse 116 and good, and the respiration 35. There was oliguria and no albuminuria. Attempts at inducing abortion were denied. Menstruation last took place at the end of June. Vaginal examination showed the cervix a little soft, but the body of the uterus was normal. On the two following days there was considerable improvement, and on the 25th the abdomen was less distended and less tender and more supple, and only a single stool was passed in 17 hours; but on the 26th her condition was distinctly worse, the features were pinched, the pulse 150 and thready, and the dyspnœa had increased. The abdomen was a little distended, tense, and a little painful. She vomited once and passed one glairy stool. A surgeon was called in and performed exploratory laparotomy. There were tracks of pus, but no collection, all over the abdomen. The maximum amount of pus and membrane was in the pelvis around the left tube. Salpingitis was considered the source of the trouble and total hysterectomy was performed. Death occurred three hours after operation. The uterus was found normal, the tubes a little enlarged, but without any gross lesions. At the necropsy the intestines were found injected and covered at numerous points with fibrino-purulent membrane. The whole intestine was filled with greenish-grey mucous liquid. It was then ascertained that on the 15th the patient had visited a professional abortionist, but what had been done was not known. Evidently the peritonitis was of genital origin and due to manœuvres to induce abortion. The intensity of the diarrhœa and the slightness of the symptoms of peritonitis suggested enteritis. Slight or moderate diarrhœa is recognised in pneumococcic and certain septic forms of peritonitis with profound intoxication, particularly streptococcic peritonitis. This diarrhœa is serous or glairy and often fœtid. But in these cases the ordinary signs of peritonitis—vomitings, abdominal pain and hyperæsthesia, very rapid, feeble pulse, and hiccough—render the diagnosis clear.

T.N.T. IN THE ANIMAL BODY.

T.N.T. poisoning has fortunately lost most of its immediate practical interest,[1] but the study of its remote effects on the body yielded results of sufficient interest to warrant a full inquiry. The outcome of this inquiry is now before us in a special report,[2] containing the most recent observations. Approach has been made from the point of view of the clinical features, toxicology, and biochemical evidence. The net result tends to show that the workers in these separate fields of investigation come to similar conclusions as regards certain aspects of the condition. The outbreak of toxic jaundice amongst workers in munition factories revealed the fact that the trinitrotoluene itself was the causative factor, and this was all the more surprising since up to this time it had been regarded as a more or less harmless substance. Naturally impurities in the trinitrotoluene were at first looked upon as the cause, but these have been proved to play no part in the production of toxic jaundice. The knowledge gained as a result of this scientific inquiry is of undoubted value, and opens up a field of investigation into the effects on the liver of closely allied substances. Trinitrotoluene is prepared by nitrating toluol, a compound produced from the distillation of coal-tar. It is possible that a number of closely related chemical compounds derived from the same source may exert a similar action on the liver. Their use in medicine is being extended daily, and we want to know their exact action on the body, particularly on the liver, and whether this action is similar to that produced by T.N.T. It is in this respect that the present report offers such valuable information and suggestions, and therefore merits careful attention.

Dr. W. J. O'Donovan contributes a long memorandum on the subject, and deals with the historical, technical, administrative, and clinical aspects of the problem.

His paper affords an excellent illustration of the value of combined work in approaching such a problem. The paragraph on the technical side is of interest, particularly as illustrations are given of the method of filling shells with T.N.T. Amongst the clinical features observed were toxic gastritis, toxic jaundice, dermatitis, and anæmia, the latter in the more severe forms being of the aplastic type. The workers who suffered from dermatitis, as a general rule, did not develop toxic jaundice or anæmia, and in this condition susceptibility undoubtedly played a very large part in its production. In the latter months of the war T.N.T. in the form of a fine yellow powder was mixed with ammonium nitrate (80 per cent.), making the resulting mixture (amatol) much more hygroscopic, and it was with the use of this mixture that the skin lesions predominated. It appears therefore that this mixture was absorbed by the skin, and its moist nature would naturally act as an additional aid to its absorption.

The occurrence of toxic gastritis is of interest, especially as it was observed so frequently in munition factories, and was of outstanding importance. The symptoms were pain (colicky in character), nausea, vomiting, constipation, and cyanosis of lips and tongue. These were the typical symptoms of poisoning by coal-tar derivatives, and convalescence appears in many cases to have been prolonged. It is more than probable that such cases may have received considerable damage to the liver, besides the gastric mucous membrane, and yet insufficient to produce actual jaundice. That coal-tar derivatives do actually induce necrosis in the liver is well known, and this may be in the form of circumscribed patches and so escape detection. The damage is still there and may show itself after a lapse of time, which may be months or years. A case was reported recently where a patient had received salvarsan treatment, and was operated upon subsequently for condylomata. The patient died after the anæsthetic, and post mortem a number of atrophied necrotic patches were found in the liver. Apart from slight jaundice following the salvarsan treatment there was no evidence of any permanent liver damage. The importance of the toxic gastritis cannot be too strongly emphasised, and any cases known to have suffered from this form should be followed up and observed. The production of cirrhosis of the liver and pernicious anæmia may receive a possible explanation on similar lines to the remote effects of T.N.T. poisoning. This latency in the production of toxic effects was a characteristic feature of toxic jaundice, around which, of course, most of the interest connected with T.N.T. poisoning lies. This is well illustrated in the case published by Professor E. Glynn, of Liverpool, the latency being nine months, and a post-mortem examination yielded evidence of extensive focal necrosis affecting about a third of each liver lobule. This toxic jaundice appears to have developed insidiously and with very slight symptoms. The earlier the cases were removed from the factory the better was the prognosis, but there was no constancy between the severity of the symptoms and the ultimate outcome of the case. All the evidence given points to the fact that the T.N.T. was capable of producing necrosis in the liver without producing any grave symptoms, hence the difficulties that arose in diagnosis. There was no simple test that could be applied to determine the extent of liver damage in any given case. A noteworthy feature was the absence of Webster's reaction in the urine of patients with toxic jaundice, which will be referred to later. The exact factor or factors which determined the onset of toxic jaundice are at present unknown, but the possibility of an intercurrent infection or lowered resistance is discussed by Dr. O'Donovan.

Dr. G. A. Wyon reports his results obtained on animals who received large doses of T.N.T.

With such doses hepatic degeneration was produced in cats, rabbits, rats, and monkeys. Chronic poisoning with small doses of T.N.T., however, did not produce any such effect. The comparison is made with poisoning by alcohol, chloroform, and tetrachlorethane, and Dr. Wyon concludes that there is a second unknown factor which probably coöperates with T.N.T. in producing fatal poisoning in man. The animal experiments, however, did not throw much light on the poisoning effects as observed in man, and illustrates one of the great difficulties encountered in this research.

Mr. T. A. Webster contributes an interesting account of his work on the metabolism and excretion of trinitrotoluene.

The question of how to detect small quantities of T.N.T. in the urine of workers exposed to this compound was satisfactorily settled by Webster, and the discovery of the test is due to his labours. The modification of the test whereby a beautiful blue colour is obtained was independently discovered by F. Tutin and described in THE LANCET, 1918, ii., 554. The chromogenic body—viz., azoxy-di-nitrotoluene—is excreted in the urine, and is responsible for the Webster test, and presumably formed in the kidney. It is here conjugated with glycuronic acid and excreted in the urine. Attempts to obtain the chromogenic substance from the blood or organs failed.

Dr. H. H. Dale deals with the fate of T.N.T. in the animal body and the attempts made to trace the changes which T.N.T. undergoes before being excreted as the chromogenic substance, the only compound so far isolated with certainty from the urine.

[1] Trinitrotoluene Poisoning: Officially Communicated by the Ministry of Munitions. THE LANCET, 1916, ii., 1026.

[2] Medical Research Council. Special Report Series. No. 58. 1921. Price 3s.

The significance of the Webster test is emphasised, especially as a signal of danger of T.N.T. poisoning. The absence of this reaction from the urine may be taken as an ominous sign. The chromogenic substance appears to represent the safest point at which reduction of T.N.T. is arrested. The failure of the body to excrete T.N.T. in this form may therefore provide an indication that more highly reduced forms occur, and with them severe intoxications.

Dr. P. N. Panton deals in his two reports with his experimental work on animals, and the pathological changes induced in man by T.N.T. poisoning.

In the experimental work he collaborated with Dr. Harold E. Bates, and Dr. H. M. Turnbull has added very complete reports upon the histological changes which he found in the experimental animals, and also in man. In only two animals was it possible to induce changes akin to the aplastic anæmia and toxic jaundice as met with in man. The aplastic anæmia and the toxic jaundice were not directly due to hæmolysis by the poisonous action of T.N.T. The extreme reduction of the blood-forming bone-marrow was the chief effect of the poison in the cases of aplastic anæmia. The cell-count was thus that of a rapid progressive primary anæmia with a high colour index. The observations on the macroscopic and microscopic changes in the liver in toxic jaundice due to T.N.T. are of more than passing interest. The question as to whether permanent liver damage occurred in the cases which recovered is also discussed. The evidence so far obtained leads to the view that recovery from minor liver damage is the rule, and is non-progressive. With severe damage to the liver there was, however, evidence of a progressive degeneration with the occurrence of toxic jaundice many months after exposure to T.N.T.

The report is a testimony to the value of scientific coöperation, and if the cases of T.N.T. poisoning are happily no longer existent, there are many conditions which closely resemble it and require investigation. The effects of a number of liver poisons have still to be elucidated, especially salvarsan and its numerous substitutes, and further light may thus be thrown upon the various manifestations of T.N.T. poisoning described in this report.

GUSTAV KILLIAN.

In the death of Professor Gustav Killian, which occurred last month, rhino-laryngology has sustained the loss of one of its most brilliant workers. Born in Mayence in 1860, he studied at Strasbourg, Heidelberg, and Berlin under Krause, Jurasz, and Fraenkel; in 1900 he became professor of diseases of the nose, ear, and throat in the University of Freiburg-in-Breisgau, and in 1911 succeeded Professor B. Fraenkel in the University of Berlin. Killian was an original worker of extraordinary fertility, and will long be remembered for his association with the most notable advances in the technique of his specialty; especially remarkable is his work on direct examination of the larynx, trachea, and bronchi, on suspension-laryngoscopy, on submucous resection of the nasal septum, and on the "Killian" operation on the frontal sinus. Many English laryngologists will remember his visit to London in May, 1914, when he delivered the Semon lecture and demonstrated his method of suspension-laryngoscopy. Foremost among his pupils are Brünings and v. Eicken. His name will remain a landmark in the history of rhino-laryngology.

THE NON-OPERATIVE TREATMENT OF SURGICAL TUBERCULOSIS.

The discussion at the Medical Society of London on March 7th served to emphasise what has recently been pointed out by Mr. G. R. Girdlestone and others in our columns—namely, the inadequate provision in this country for dealing with the crippling disabilities of children. Mr. Girdlestone himself found,[1] from an analysis of the case-sheets of more than 12,000 youthful cripples, that in 35·4 per cent. of them the occasion of the crippling disability had been non-pulmonary tuberculosis. At the discussion Sir Anthony Bowlby, speaking for surgeons in general, justly pointed out that it was impossible in these, or indeed in any other cases, to eradicate the tubercle bacillus by operation. If it could be done at all, that was a thing which could only be done by the patient himself. But, on the other hand, much more than passive treatment was needed for this class of case. Mere convalescence in the open air was insufficient, for a child with a tuberculous hip needed appliances and other forms of special treatment. Mr. T. H. Kellock in his contribution regretted that efforts so far had been mainly directed towards building up the constitution in these cases of surgical tubercle, whereas little or nothing had been done to try to treat the disease itself. He also saw the necessity of combining local and constitutional treatments. Mr. W. H. Trethowan showed the difficulties of the orthopædic surgeon called upon to treat tuberculous disease of bones and joints in the busy out-patient department of a big general hospital. Some cases did well even without the benefit of a stay in the country, but often the most modern and efficacious methods of preventing and correcting deformity were in out-patient practice vitiated in results by bad home circumstances. All who are called upon to deal with these cases naturally turn for guidance to the experience of the Treloar Cripples Hospital at Alton or to that of the Rollier Clinic at Leysin; but the suggestion of scattered orthopædic clinics made by the Central Committee for the Care of Cripples should not be forgotten. Every area in this country should be served by a hospital for crippled children.

ANGINA PECTORIS IN DIABETES.

According to Dr. Max Kahn,[1] physician to the Beth Israel Hospital, New York, comparatively little attention has been given to the cardio-vascular changes present in diabetes, angina pectoris especially being overlooked. Unless granular changes in the kidney are also present, the diabetic patient usually has a normal or low blood pressure. Attacks of angina pectoris may nevertheless be the chief complaint of a middle-aged diabetic patient. Although the pain may not be excruciating, it may be sufficiently severe to stop whatever work the patient is doing. A remarkable feature of the attacks is that they do not occur when the sugar tolerance is not exceeded. A high blood-sugar with glycosuria will frequently cause recurrence of the attacks. Dr. Kahn suggests that the pathological changes in the myocardium responsible for the angina result from a lowering of the glycogen storage in the fibres of the bundle of His, which are normally richer in glycogen than the ordinary cardiac fibres. Electro-cardiograph tracings of diabetic patients with angina pectoris show an inversion of the T-wave in one or more of the three leads, which, as Willus has recently pointed out, is usually due to some pathological change of the myocardium. Of three cases of diabetes reported by Dr. Kahn two had a low blood pressure and attacks of angina pectoris, while in the third there were high blood pressure and albuminuria, but the patient did not complain of any cardiac oppression.

THE MANCHESTER RADIUM INSTITUTE.

The report of the Manchester and District Radium Institute for the year 1920 consists for the most part of abstracts of two papers read before the Royal Society of Medicine last year. The first of these concerns carcinoma of the cervix, the second the treatment of exophthalmic goitre; both should be of value to practitioners who missed the opportunity of reading the original communications. Of original work Dr. G. E. Loveday furnishes a report on the blood of radium workers based on examinations carried out in the institute during the past 14 months. Two cases are described in detail, one being that of a female worker, who had handled radium for five years. Unfortunately, no indication is afforded as to the precise nature of her work—whether she was engaged in making or fitting emanation apparatus, or in applying it to patients. Thus no judgment can be formed as to the amount of gamma radiation received, a fact upon which other investigators lay particular stress, as the blood changes are believed to be the expression of the cumulative action of small doses of gamma rays. The same criticism applies to the case of the male worker. Both cases showed leucopenia; in the case of the female worker it was extreme, but the leucocyte count resumed its normal level nine months later after a period of rest. A summary of work done at the institute shows that 834 fresh cases were seen during the year, 562 of them being malignant, and of these, 65 cases (exclusive of rodent ulcer) are stated to have been "free from signs and symptoms of disease at the end of the year." Such results are encouraging, although they should be read along with Dr. Arthur Burrows's statement that "nearly half the cases reported well at the end of the year in my annual reports recurred subsequently," and it is probable that with the passage of time other cases may show signs of recrudescence. Interesting suggestions are made with reference to prophylactic irradiation, and the question is raised whether this procedure should be adopted some time before, at, or some little time after the operation. A positive pronouncement on this point would be welcome. Dr. Burrows discusses the possibility of modifying the screens now in general use, and refers to Janeway's method of burying unscreened tubes in tumours as an indication of the fact that heavy screening is by no means essential in treatment. He states that brass and silver are, on the whole, the best methods to be employed. This endorses the experience of many other workers, who agree that silver is the most generally useful screen. A photograph is given of the new Radium Institute, to which it is hoped to transfer the work early in the present year.

SYPHILIS OF THE PANCREAS.

Dr. Udo J. Wile,[1] professor of dermatology and syphilology of the University of Michigan, remarks that in spite of Neumann's statement in 1899 that the diagnosis is never made during life or at least without operation, a number of cases are on record in which undoubted syphilis of the pancreas was diagnosed intra vitam. Although most authorities hold that the condition is exceedingly uncommon, Sallis, who collected 15 cases in 1913, asserts that the condition is not so rare, and states that syphilitic lesions of the pancreas occurred 45 times in 100 cases of abdominal syphilis. Warthin also holds that chronic interstitial pancreatitis is one of the most frequent visceral lesions found at necropsies in cases of latent visceral syphilis. Syphilis of the pancreas may occur in a sclerous and a gummatous form; a combination of the two forms is also found. The symptoms of syphilitic pancreatitis differ but slightly from those of any other pancreatic disease, and the pancreas is so seldom affected alone that the symptoms are frequently masked by those of involvement of the other viscera. The few points suggestive of syphilis when the pancreas is the seat of disease are jaundice without other cause, glycosuria, and tumour of the pancreas without cachexia. The diagnosis is extremely difficult. Except for the predominance of glycosuria, which occurs in about 50 per cent. of the cases, and the relatively mild cachexia in association with a large palpable tumour, there are no definite criteria, according to Dr. Wile, to differentiate syphilis of the pancreas from cholelithiasis and from other forms of pancreatic disease, such as carcinoma or chronic interstitial pancreatitis. The association of hepatic disease, however, is strongly in favour of syphilis, and the therapeutic test is in most cases the most valuable guide. Although Neumann regards the prognosis as unfavourable, inasmuch as most of the cases are recognised only at autopsy, Dr. Wile has collected 10 cases in which complete recovery was reported as the result of administration either of salvarsan, mercury, or iodide, or of mercury and iodide combined.

"IDIOPATHIC" DILATATION OF THE URINARY BLADDER.

IN a recent issue of THE LANCET (March 12th, p. 534) Dr. S. R. Tattersall recorded an example of those curious cases of dilatation of the urinary passages without any discoverable mechanical or organic obstruction to the exit of urine. The instance is that of a youth, 18 years of age, who died with renal fibrosis, and in whom the bladder was distended and hypertrophied, notwithstanding the fact that micturition was unimpeded and that a rubber catheter could be passed without difficulty; the urine, which was acid, contained no blood or pus. A similar phenomenon, mutatis mutandis, is encountered elsewhere, and is, perhaps, best known in the œsophagus under the names of idiopathic dilatation, œsophagectasia, and achalasia. Now that the diagnosis of this form of œsophageal dilatation has been rendered easy by skiagraphy (after the administration of bismuth mucilage), the number of such has augmented, the increase being, of course, apparent only, and due to the development of more accurate methods of diagnosis. In the large intestine a like end-result has been long known, once as "idiopathic" and at present as "megacolon," the change in nomenclature having added, however, no further light as to its causation. These various dilatations are "idiopathic" in the meaning that they stand apart in their kind, and do not admit of explanation by any of the commoner obstructions which lead to similar distension. That they are neuromuscular in their essential nature, however, may be assumed without much hazard, using this term in a broad sense; for under such, more than one conception in detail is possible. The hypothesis that the dilatation arises from a fault in coördination between the propelling musculature and the relaxation or active dilatation of a corresponding sphincter, is that at present in favour. The name achalasia (failure to open) was devised in order to exclude sphincteric closures due to hypertonic contraction or spasm. The latter process may be excluded by the fact that no hypertrophy of the sphincters is found, even after the lapse of many years, during which the dilatation of the structure behind has been proceeding. The existence of a sluggish reflex is another possible element in the neuromuscular fault, the origin of the normal reflex being the distension of the viscus, which latter may not be incited to discharge its contents until the internal pressure reaches a degree which in health would be excessive. The existence, lastly, of a primary ganglio-neuritis of the intraparietal nerves of the viscus concerned is a further supposition of which the truth can be proved only by rigid histological demonstration.

Dr. Norman Walker, of Edinburgh, has been appointed Chairman of the Scottish Board of Health Consultative Council on Medical and Allied Services in succession to Principal Sir Donald MacAlister, K.C.B.; and Dr. John Yule Mackay, Principal of University College, Dundee, has been appointed Vice-chairman in succession to Dr. Walker. While relinquishing the chairmanship of the Council, Sir Donald MacAlister will continue to give his services as a Member of the Council.

THE LANGHAM TELEPHONE EXCHANGE:

MEDICAL MEN'S NEW NUMBERS.

WE have received notice of the following additional transferences from the Mayfair to the Langham Exchange:—

Mayfair.	Subscriber.	Langham.	Mayfair.	Subscriber.	Langham.
4054	Carlill, Hildred	2134	1118	Matthews, John	1115
7021	Mason, M. S.	1295	5387	Daly, Ashley	1667
1993	Saunders, Arthur	1913	4861	Steele-Perkins, G.	1775

The speedy appearance of the new Telephone Directory will, we hope, make further announcements unnecessary.

A POLAR EXPEDITION.

BY A. H. MACKLIN, O.B.E., *M.C.*, M.D. VICT.,
LATE SURGEON TO THE IMPERIAL TRANS-ANTARCTIC EXPEDITION.

IN view of the recent announcement by Sir Ernest Shackleton of a new expedition to the Arctic some of its medical aspects and some account of the surgeon's work may be of interest.

Purely medical work forms a very small share of the total duties of the surgeon. All members of an expedition must take part in routine duties; they must be prepared to help in the work of the ship, wash down decks, take a trick at the wheel, even to take a turn as "Peggy," assisting in the galley and washing dishes. Later their duties may include temporarily those of sledge-pullers.

Once the general duties have been carried out, each man must be prepared to attend entirely to his own wants, and must keep in repair all his personal gear. In addition he has his own special work to perform: the zoologist and botanist make and supervise the collection of animals and plants, the geologist makes his study of ice and land formations, and so forth. As each member of the expedition has to be physically fit, and is selected partly for his qualities of wind and limb, the duties of the surgeon in the ordinary way are light. His opinion, however, is sought on diverse unexpected matters, such as the health of the sledge-dogs and the quality of the meat of seals, penguins, and sea-birds generally.

The Welfare of the Dogs.

Veterinary work is of the highest importance to the expedition, for the dogs form the traction power of the sledges, and the loss of any one of them is serious. Their chief disabilities result from fighting. Many of these dogs seen in the ordinary way and with stomachs well filled with a mixed dietary, are tractable and peaceable, but when at work, or on a definite ration, often of freshly killed meat, they are fierce to a degree, and though submissive to their drivers (a point of policy) fight amongst each other so furiously that serious injury and disability result unless they are separated at the onset. Injuries from this cause cannot be absolutely eliminated, though it is a point of interest that dogs which have worked together in a team for some time rarely fight. When two strange teams meet, however, there often ensues a battle royal, in which every dog of each team participates. In dealing with wounds and external injuries of the dogs it is necessary so to dispose the animal that it cannot interfere with the repair process, and to secure this considerable ingenuity is often called for on the part of the surgeon. My own experience in the Antarctic has shown that wounds in dogs heal readily and well, and that good results can be obtained from fractures, even those of such bones as the humerus, which is not by any means so "getatable" for treatment as the human humerus.

The chief sources of sickness amongst sledge-dogs are undoubtedly parasites. External parasites are easily dealt with by isolation and washing with fairly strong antiseptics—e.g., carbolic soap and lysol, and keeping the coats well combed and brushed. Intestinal parasites are also fairly easily dealt with, the most difficult to get rid of completely being the ordinary tapeworm. In dogs a much more drastic method can be adopted than with human subjects. When the condition has been diagnosed the animal's food is stopped and a powerful purgative is given. This in itself will often cause the passage of a large number of parasites, sometimes even the complete tapeworm. For this purpose castor oil is the most effective purge, but must be given in large doses (about 2 oz. for a dog weighing 90 lb., and more for the heavier dogs). After the bowels have been completely evacuated the vermicide is given and is followed in about 24 hours by another purgative. All food is withheld during this time, though the animal is allowed to drink or to eat snow. the fourth day food is again given. I have never any ill result from the combination of filix mas and castor oil. It is astonishing what a number of the various nematodes and cestodes an animal can carry in its intestines without marked external signs. Another parasite which I encountered in ten dogs during the last Antarctic expedition is more difficult to deal with. The animals attacked lost weight and hair, the mucous membranes were pale, and a curious hump of the spinal column exhibited itself; the animal was restless, barked at nothing, and scratched itself frequently. Post-mortem examination revealed the presence of a large, round, reddish-pink worm with a dark lateral line, 2½–3 ft. in length, known from its appearance to the sailors as "the big red snake." Sometimes two smaller worms were found. All but one were found in the abdominal cavity, the most usual site being under the right lobe of the liver or in the right epigastric fossa. In every case the worm was shut off by a thin-walled prison caused by fibrinous adhesions of the omentum. On first opening the abdomen (the incision was always made before the carcass had become cold) the worm seemed to be feebly motile. This motility lasted for a few moments only; as the examinations were always made in low temperatures, this was probably due to the inrush into the abdomen of cold air. In one other case the worm, a large one, was coiled in the pelvis of the left kidney, the cortex of which was contracted and hard. The right kidney was hypertrophied. The preserved specimens of the organs and the blood films were lost owing to the sinking of the *Endurance.* From inquiries and references made since my return I gather that the parasite was the *Strongylus gigas.*

Parasites Affecting Food-supply.

The surgeon is usually called upon to decide as to whether various portions of the animals killed for food are fit to eat. I found in the Antarctic that all of them, the seal tribe, sea-leopards, sea-elephants, &c., penguins, and the various sea-birds, suffered largely from parasites. In most cases these were confined to the alimentary tract, but in some cases I found cysts on the heart wall (*Cysticercus cellulosæ*), and some small bodies, stated by the biologist to be trematodes, free in the bile-passages in large numbers. Often in the latter case the left lobe of the liver was white and shrunken, a faint, sharp line differentiating the unhealthy from the healthy part. In these cases also, the lymphatic glands throughout the whole body were enlarged, and the capsule separated off by a thin layer of serous fluid. The spleen was often so much enlarged that it more than half filled the abdomen and was soft and flaccid.

[As in the case of the dogs, all pathological specimens and notes made at the time were lost with the ship.]

Antarctic animals depend largely upon fish for their food-supply, the other source consisting of what is commonly spoken of as "whale food," small creatures known as euphausia and a species of amphipod. All the fish obtained in these regions contained intestinal parasites in large numbers, and were probably the source of their occurring in the larger animals. I was interested to notice that the only "land" bird in the Antarctic—namely, the Paddy Bird—lived largely upon the parasites passed in the excreta of penguins. Often where penguins collected in numbers, these Paddies could be seen walking about with quick steps, hastening always to pick up the parasite before it had become frozen in the excreta. The whale forms one exception to the above. This immense animal is notorious for a very small gullet, through which one would have difficulty in passing the hand. Mr. Clark, who examined numerous specimens, found that whales lived entirely on euphausiæ, amphipods, and sometimes on squids. I have regretted that I did not examine their stomachs and intestines to see whether they contained the same parasites as the fish-eating animals.

With regard to the employment of the meat of such animals, I always insisted on the importance of first carefully removing the whole alimentary tract entire, avoiding spilling of the contents, and burying or dumping it well away from the meat. When parasites were confined to the intestines all the meat, and the liver, kidneys, heart, and brains, were used for food.

When there were any signs of disease outside of the alimentary tract I recommended that it should not be used at all, except when food was scarce, when the meat was eaten, but the internal organs thrown away.

Frost-bite.

The purely medical work consisted mainly in dealing with such small accidents as may from time to time occur amongst the party—frost-bites, small localised inflammations, cuts, fractures, extraction of teeth, &c. Frost-bite is a condition which occurs very frequently, but all members of the party quickly learn how to recognise and treat this condition, and the danger of neglect is so well known that a constant watch is kept for its onset. As is common knowledge, the parts most frequently affected are the exposed parts of the face and the extremities—the tips of the ears, the nose, the skin over the cheek bones, the chin, the fingers, and toes. It is the custom for members who are out together, or meet outside, to scrutinise each other's faces, and give warning of any appearance of frost-bite. Some men carry a small looking-glass for this purpose. In the very early stages it is only necessary to cover the part first with one warm hand and then the other, replacing each as it gets cold in the mitts. A little gentle friction may be applied, but not much, for the cuticle over a frost-bitten part of the face is easily rubbed away, leaving an extremely sore and slightly weeping surface. The practice of rubbing the part with snow, recommended in text-books, is utterly useless and extremely unpleasant. Frost-bitten fingers are easily treated by placing the hand inside one's clothing next to the skin. Frost-bite of the feet and toes is a very much more serious matter, and each individual must exercise the greatest care and watchfulness in guarding against its onset. The danger is that the parts may become frost-bitten, while the owner is quite unaware that anything is amiss or whilst he is asleep. Exhaustion adds to the danger, for not only is the local circulation impaired, but the man is not likely to be so watchful for its onset, or so ready to take prompt steps for its treatment. The toes may be unbearably cold and suddenly become comfortable. This is easily recognised if all the toes become suddenly frost-bitten at the same time, but the difficulty is that small portions of different toes are usually affected, and though there is no sensation in these parts, the toes as a whole still feel cold. To the experienced, and those on guard for it, there is, however, a feeling that everything is not quite right, when the only thing to do is to remove all foot-gear and examine the part. Frost-bitten feet may be treated by rubbing with a warm hand, and may be rubbed more vigorously than the face. The parts usually return to normal within a few minutes. If the frost-bite has been present for some time it may be necessary to persist on this treatment for a longer period. Bad cases require that a good Samaritan enclose the foot within his clothing next to the warm skin, or even relays of good (but probably blasphemous) Samaritans. Removal to a warm atmosphere and hot food and drink facilitate recovery, but care must be taken to prevent too rapid a return of the blood flow, causing choking of the capillaries, thrombosis, and a condition more difficult to deal with than the original frost-bite. It is, no doubt, the danger of this that has given rise to the treatment of "rubbing with snow." Certainly it is more justifiable in the case of the feet, and may be a good thing to teach "first-aid" students, whose natural instincts would be to warm the parts at a fire or to plunge them into hot water. Cases which do not come back to normal within a few hours of this treatment will not come back to normal at all; blisters containing straw-coloured serum or even blood may form, and then the question arises whether the slough be superficial and the patient will get off with the loss of some skin, or will death of the whole part, requiring amputation at a later stage, ensue? A case which occurred on the last Antarctic expedition produced typical dry gangrene of the toes, which were black and shrivelled, and separated by a well-marked red line from the healthy foot. Amputation was performed. The party was at that time living under an up-turned boat. During the operation the inmates were all turned out, with the exception of two invalids, one of whom, suffering from frost-bite himself, gravely looked on, wondering whether his turn would come next. It is impossible to over-emphasise the extreme importance of prompt and efficient treatment in dealing with frost-bite of the feet. It is quite a common thing where the parts have not been actually frost-bitten on the return from the cold outer air to a warm room for a sensation of severe "pins-and-needles" to occur while the circulation is returning to normal. There is here also a point of danger, for the too rapidly returning flow of blood into devitalised tissues may lead to exudation into the surrounding tissues, causing constriction of the lumen of the vessels. In a mild degree it often causes an irritable condition resembling chilblains, and is most commonly seen on the tips of the ears. Hence the advisability of not immediately warming the parts, but of letting the process take place gradually.

Advice on Foot-gear.

In dealing with frost-bite of the feet the great essential is, of course, prevention, and this is a point to which Sir Ernest Shackleton has himself given great attention, even to the very lowest detail. Frost-bite is due to the constricting influence of cold on the capillaries, so that eventually the lumen becomes obliterated. The part is entirely denuded of blood, and becomes waxy-white in appearance. The essentials of foot-gear for Polar regions are therefore: (1) to avoid any constriction of the supply of blood to the toes; (2) to have a non-conducting air-space between the toes and the outer air. The first is arrived at by wearing loose coverings to the legs, avoiding garters, and any sort of constricting bands, and by having the socks well fitting and made in series, so that when three pairs are being worn the second sock fits easily over the first, and the third easily over the other two. The outer coverings, for the sake of utility, must be well-fitting, but must be sufficiently loose and allow a non-conducting air-space between them and the feet. This is largely obtained through the socks, which, made of wool, contain a lot of air in their meshes. It is important also to see that, as far as possible, this air-space is not replaced by damp. Thus the outer covering must permit of ventilation to prevent the accumulation in the socks of perspiration moisture. Rubber boots, for this reason, are unsuitable. The outer coverings as put into use consist either of finnesko made from reindeer hide or of specially designed boots with strong leather soles and strong, closely-woven canvas tops. Felt boots are also sometimes used. Further, to obviate the difficulty of perspiration, sennegrass, which takes up moisture and dries again rapidly, is packed into the finnesko or boots each morning, and is removed each night to dry. It dries so rapidly that, if spread out, it is quite ready for use the next day. Socks are taken off always at night; no experienced explorer would ever dream of keeping on during the night the socks he had worn during the day, a temptation to which the inexperienced is very prone. It is a rather surprising matter of experience that socks placed during the night between one's jersey and the underclothing will have dried out considerably by morning (even a wet box of matches can be rendered fit for use in this way). They cannot be left out in the open air because, with the slight moisture in them from perspiration, they would freeze absolutely stiff in the shape in which they had been hung out.

Oils and grease, which are regarded by a great many people as being non-conductors, and "fine stuff to keep you warm," should be avoided as much as possible, for they conduct cold readily. Everything should be done as far as possible to eliminate them both from clothing and from skin. I have nothing to say here with regard to the use of whale oil in the army; the pros and cons are numerous, and space does not permit me to enter fully into the question; but as a result of observations and experiments, in the Antarctic, in France, on the Italian mountains, and in Northern Russia, I am fully convinced that the ideal to aim at for the prevention of frost-bite is dryness and the exclusion of fats and oils.

From the point of view of an expedition this may be illustrated in many ways. During a visit to the whaling station of South Georgia, where whale oil abounded, I made a practice of rubbing the oil into my boots, with the object of making them warmer and more waterproof. I discovered that it had the opposite effect. The whalers informed me that this was a matter of common experience amongst them, and that they made a practice of removing as much whale oil as possible from their boots each night. Whilst in the Antarctic it was often my duty to flense and cut up seals. In the process my left hand grasped the seal and became well anointed with blubber oil. My right hand held the flensing knife and was not so anointed. Following the operation I wiped my hands with snow, which did not completely remove the grease, dried off surplus moisture, and replaced them in mitts. When returning to camp my left hand was always cold, whereas the right hand remained comfortably warm.

After the loss of the *Endurance*, with stores, it became necessary for members of the party to wear, without change, the same clothes for the best part of a year. Parts of them became very greasy; the cold could be felt readily "striking through" these greasy parts in marked contradistinction to the non-greasy parts. Socks which had been worn for some time and become slightly greasy were not so warm as clean dry socks.

Scurvy.

With regard to scurvy, a disease which has interfered with many Polar expeditions, much new work has been done in recent years, and the numerous investigations and results published in medical papers. From the point of view of a Polar expedition it is wise to regard the disease as having two different causes: (1) The deficiency of a vitamine; (2) a gastro-intestinal intoxication, or the direct action of small but potent ptomaines contained in badly preserved meat. In spite of the extremely convincing work on vitamines there is still the possibility that this latter factor may come in, and only the very best preserved foods, obtained from reliable firms, should be used.

Sir Ernest Shackleton has always realised the importance of variety in food, both from a mental and physical point of view. Thus in the Antarctic expedition one could never tell the day of the week by the food supplied, and some new and fresh dainty was constantly appearing. Even before the loss of the *Endurance* in the days of plenty fresh meat was constantly served, and the cooking was always good.

Some Questions Answered.

A question often put to me by medical men is with regard to the functions of defæcation and micturition. These are performed in the usual way, though certainly often under the most uncomfortable conditions. I have never seen perineal or anal frost-bites, although it is reported that one of the men who accompanied Sir Ernest Shackleton across South Georgia incurred frostbite of the penis. It certainly was not serious, and produced no permanent disability. Many times men who went outside in cold, and especially in windy, weather, returned extensively frost-bitten in the face and hands and feet, but not in the private parts. In the case of severe and prolonged blizzards it might be necessary to defæcate in a tent, a hole being dug and instantly refilled with snow; but the majority of men will prefer to face the most unpleasant weather conditions out of doors. This suggests a small but important point: in cases of constipation the greatest care must be exercised in purgation not to produce too violent a result. Should a sudden blizzard arise it would be the greatest hardship to a man to have to face the violence of the elements too many times.

Another interesting point is that members of the Antarctic expedition, owing to the loss of the *Endurance*, were compelled to go for a prolonged period (about ten months) without a wash or a change of clothing. I have been asked how this affected the skin. It was found at the first hot bath that the skin round the knees and elbows, where the clothes rubbed, had become begrimed and required two or three good scrubbings; for the rest the skin was beautifully white and unusually soft and satiny to the touch. This condition lasted from two to three months, when the skin gradually returned to normal. Nasal catarrh, the so-called "cold in the head," did not exist; there was not one case till we returned to civilisation, when almost without exception every member was attacked and had difficulty in throwing off the condition. There is another point on which I have been asked—namely, growing a beard. I think it is almost universally agreed upon amongst modern explorers that a beard is not a good thing. True, it has certain advantages in that it is warming and protects the face and neck from winds. The great disadvantage is that moisture from the breath issuing from mouth and nostrils impinges on it and freezes, forming in a short time a solid mass of ice on the face which in itself is not comfortable, and when one enters a warm room or a sleeping-bag thaws out with unpleasant results. Stefansson ("My Life with the Eskimo") advocates clean shaving, but in this heroic measure few others will be found to agree, and is, of course, quite out of the question when performing a sledge journey. The custom most commonly adopted is close clipping with the ordinary fine barbers' clippers, performed at least once weekly.

The cold keen air of polar regions acts on the body like champagne, and fills one with a joy of living not experienced in tropical or even temperate climates. Both man and dogs gain in bodily vigour the further they penetrate over the Circle. Appetites are increased, and on the plain well-cooked food everyone puts on weight. The dogs become much more lively, a condition manifested by more fierce and frequent fighting; their coats grow thicker, and the clamour at feeding time becomes absolutely riotous. Every morning shows them madly keen to get into harness, and though hard worked and rigidly disciplined, they show a joy in existence rarely exhibited by the leisured animal at home. On the other hand, it is a bad country to be ill in. There are few comforts such as we know them, no warm and pleasant sick-rooms, no cool, clean sheets, or gentle women. In cases of sickness amongst the dogs, facilities do not permit of artificially warmed housing; and they rely on their own body heat and the insulation of their thick coats. It is here that the value of the bushy tail is seen, and also the habit, well known, even in domestic dogs, of twisting round and round in a circle before finally settling down to rest. The sledge-dog does the same in the snow as the pet dog does on the carpet, producing thereby a small sheltered hollow into which he coils himself, and, curling his bushy tail over the unprotected parts of his face, presents when asleep the appearance of a round ball of fur. When from whatever cause the animal's vitality is lowered and the temperature subnormal, it is unable to resist the intense cold, and unless taken to the lee of a warm pipe, or placed in some improvised warm shelter, rapidly succumbs.

It may be of interest to mention that dogs can exist when buried under several feet of snow. On one occasion, after a two days' blizzard, I found the whole of my dogs buried in varying depths of from 4 to 8 feet in a large snow ramp; yet when dug out, except that they were rather sluggish and more difficult than usual to rouse, they were perfectly normal. In ice regions it is unnecessary to water dogs—they obtain all that is required by eating snow.

One more point of interest: salt ice when piled up has the peculiar property that after two to three days the salt leaves the top pieces in the pile, so that they become quite fresh and can be melted down for use as drinking water. But for this property existence on floe ice would be impossible.

There are times in these inhospitable regions when one hates them and the longing for home is intense. Yet the return to civilisation is not altogether unmingled with regrets, nor is the prospect of another visit devoid of a feeling of "uplift" and pleasurable anticipation.

A NURSES' TRAINING COLLEGE IN BRUSSELS.—In memory of Edith Cavell and Mme. de Page the Rockefeller Foundation has given Fr.43,000,000 for the establishment of a training college for nurses in connexion with Brussels University Medical School.

VITAL STATISTICS OF LONDON

DURING FEBRUARY, 1921.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 10·0 per 1000 of the population, estimated at 4,531,971 persons in the middle of 1920; in the three preceding months the rates had been 15·2, 11·9, and 10·4 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in Chelsea, the City of Westminster, St. Marylebone, Hampstead, Holborn, and Lambeth; and the highest in Fulham, Bethnal Green, Poplar, Battersea, and Greenwich. The prevalence of scarlet fever was about 10 per cent. less than in the preceding month; this disease was proportionally most prevalent in Hammersmith, Finsbury, Bethnal Green, Stepney, Poplar, Southwark, and Bermondsey. The Metropolitan Asylums Hospitals contained 3799 scarlet fever patients at the end of the month, against 5503, 4729, and 4112 at the end of the three preceding months; the weekly admissions averaged 464, against 780, 590, and 489 in the three preceding months. Diphtheria was slightly more prevalent than in the preceding month; the greatest proportional prevalence of this disease was recorded in Paddington, Islington, Shoreditch, Bethnal Green, Battersea, and Greenwich. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 2604, 2615, and 2648 at the end of the three preceding months, numbered 2766 at the end of February; the weekly admissions averaged 333, against 360, 316, and 319 in the three preceding months. The prevalence of enteric fever was appreciably less than in any of the six preceding months; of the 14 cases notified during the four weeks ended Feb. 26th, 3 belonged to Stepney, 2 to Islington, 2 to Paddington, and 2 Wandsworth. There were 9 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 16, 15, and 11 at the end of the three preceding months; the weekly admissions averaged 2, against 3, 2, and 3 in the three preceding months. Erysipelas was proportionally most prevalent in Paddington, Fulham, Bethnal Green, Poplar, Southwark, and Deptford. The 25 cases of puerperal fever included 3 in each of the boroughs of Hammersmith, Islington, Lambeth, and Deptford, 2 in Stepney, and 2 in Poplar. The 17 cases of cerebro-spinal meningitis included 2 in Stepney, 2 in Southwark, and 2 in Lambeth; while the 2 case of poliomyelitis notified during the month belonged respectively to Hammersmith and Hackney.
